Mechanism of Action of Eosin-Methylene Blue Agar in the Differentiation of *Escherichia coli* and *Enterobacter aerogenes*

R. S. HORVATH and M. E. ROPP

Department of Biology, Bowling Green State University, Bowling Green, Ohio 43403

The mechanism involved in the action of eosin-methylene blue agar (EMB) in differentiating *Escherichia coli* from *Enterobacter aerogenes* was investigated using prototrophic strains of these organisms and a Lac auxotroph, *E. coli* X-961. The final pH of the EMB agar resulting from growth of these organisms at the expense of lactose was shown to play a critical role in the differential action. An EMB complex, which formed under acidic conditions, appeared to be involved in the differential action of this medium. The molecular weight of the complex indicated an eosin to methylene blue ratio of 1 to 1. Ultraviolet and infrared spectral data indicated the occurrence of an amide bond between the dyes when complexing occurred. On this basis, a mechanism for complexing of eosin and methylene blue, under acidic conditions, was proposed.

The use of eosin-methylene blue (EMB) agar as a differential medium for the colon-typhoid-dysentery group has become well established since its introduction by Holt-Harris and Teague (2) in 1916. The medium contained the dyes eosin and methylene blue, which yielded a sharp distinction between lactose- and non-lactose-fermenting organisms.

Two years later, Levine (3) employed a modification of the original EMB medium and concluded that the modified EMB could be used to differentiate lactose fermenters from non-lactose fermenters.

Although the medium had been used extensively since its introduction, the mechanism of its differential action was not known. Wilson (6), in a review of differential staining by mixtures of eosin and methylene blue, called attention to a dye complex which formed under acidic conditions. It was proposed that such a complex might be responsible for the differential action of EMB agar.

Wynne, Rode, and Hayward (7) assumed that the differential action of EMB was a direct function of the acid produced during fermentation. Pathogens belonging to the genera *Salmonella* and *Shigella* were compared with the nonpathogens *Escherichia coli* and two *Enterobacter* species, and it was concluded that the pathogens could not ferment lactose to produce a sufficiently low pH to result in colored colonies on EMB, whereas the nonpathogens could reduce the pH to a level at which colored colonies resulted.

The mechanism by which EMB agar differentiated *E. coli* and *Enterobacter aerogenes* remained unknown. To demonstrate the mechanism of this differential action, the effect of pH was investigated. The molecular structure of the dye complex was determined, and a mechanism for formation of the dye complex was proposed.

**MATERIALS AND METHODS**

**Bacterial strains and media.** The strain of *E. aerogenes* was supplied by M. M. Brent, and the culture of *E. coli* wild type was obtained from S. Harmon, both of the Department of Biology, Bowling Green State University. The culture of *E. coli* X-961, a lactose-negative auxotroph, was supplied by R. Curtiss III of Oak Ridge Laboratories, Oak Ridge, Tenn.

Stock cultures were maintained on cystine Trypticase agar stabs (Difco Laboratories, Detroit, Mich.) at 15 C. Experimental cultures were grown at 37 C for 18 to 24 h in broth containing 1% lactose, 1% peptone, and 0.2% dipotassium phosphate. EMB broth contained 0.04% eosin Y (Matheson Coleman and Bell Co., Cincinnati, Ohio) and 0.0065% methylene blue (National Aniline and Chemical Co., N.Y.) in addition to the above constituents. Solid media were prepared by adding 2% agar to the basal formula. All media were sterilized by autoclaving at 121 C and 15 pounds pressure for 15 min.

**Methods.** A Corning pH meter, model 7 (Corning Scientific Instruments) with Beckman pH electrodes (Beckman Co., Chicago, Ill.) was employed for pH determinations. The relative pH produced by each organism on solid media was determined by use of the indicator bromothymol blue. The medium contained...
0.0016% bromothymol blue, 1% peptone, 0.2% dipotassium phosphate, 2% agar, and either 1% lactose, 1% glucose, or no sugar. The color of the dye at the end of 24 h of growth at 37 C served as an indication of final pH. The effect of pH on formation of the dye complex was investigated by employing buffer concentrations of 0.0, 0.2, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, and 1.0% in the EMB medium. All solutions were examined visually for the presence of a precipitate, and the pH was determined as above. The pH necessary to complex the dyes was also determined by titration of EMB broth with 0.01 N HCl.

The molecular weight of the dye complex was determined by the molal freezing point depression (5) using d-camphor as the solvent. The dye complex was prepared by reducing the pH to 3.5 with 1.0 N HCl. The precipitate was harvested by centrifugation at 10,000 × g for 10 min and washed 10 times with distilled water to remove traces of unreacted eosin and methylene blue. For determination of the freezing point depression, a Buchi melting point instrument (Rinco Instrument Co., Greenville) was employed.

Ultraviolet spectra of the complex, eosin methylene blue, and a noncomplexed eosin-methylene blue solution were determined using a Beckman DB-G spectrophotometer (Beckman Co., Chicago, Ill.). The infrared spectrum of the complex was examined as a KBr macro pellet with a Perkin-Elmer 337 double-beam spectrophotometer (Perkin-Elmer Co., Norwalk, Conn.), as were the spectra of eosin and methylene blue.

RESULTS AND DISCUSSION

Because the differentiation of pathogenic microorganisms from nonpathogens by EMB agar was dependent on the amounts of acidic products resulting from the fermentation of lactose (7), it appeared that this mechanism might also account for the differentiation of E. coli and E. aerogenes. Results obtained with bromothymol blue as an indicator of final pH of the culture medium indicated that E. coli did produce a strongly acidic condition during growth at the expense of lactose, whereas E. aerogenes yielded a much less acidic medium. The reaction exhibited by E. coli X-961 was similar to that obtained with E. aerogenes. This observation was verified by measurement of pH after growth of E. coli and E. aerogenes in lactose broth. E. coli reduced the pH of this medium from the initial pH of 7.1 to 4.9 in 24 h, whereas E. coli X-961 yielded a pH of only 6.4, and E. aerogenes reduced the pH to 5.3 in the same time period. These results were consistent with those obtained by Wynne et al. (7) and established a quantitative difference in the final pH resulting from fermentation of lactose by the microbial species in question.

Titration with 0.01 N HCl indicated that the complex formed at a pH of about 4.9, thereby establishing the significance of the pH difference observed above.

If pH is the critical factor in formation of the dye complex, growth of E. aerogenes on unbuffered EMB agar should result in a reaction typical of E. coli. The effect of pH on formation of the dye complex was observed by varying the buffer concentration from 0.0 to 1.0%. Growth of E. aerogenes on EMB agar containing no buffer did result in the formation of a green metallic sheen, and the pH of the corresponding EMB broth was found to be 4.8. This sheen was not produced by E. aerogenes on media containing a phosphate buffer. E. coli, however, was capable of producing the typical reaction at buffer concentrations up to 0.5%. Thus it appeared that pH was the critical factor in the formation of the green sheen observed with E. coli on EMB agar.

![FIG. 1. Ultraviolet spectra of the dye complex (solid line) and the eosin-methylene blue uncomplexed solution (broken line).](image-url)
The metallic appearance of *E. coli* colonies seemed to result from the formation of a dye complex under acidic conditions. The molecular weight of this complex was determined to be 1,016, indicating that the dyes eosin and methylene blue occurred in this complex in a ratio of 1 to 1.

The structure of the complex was inferred from ultraviolet and infrared spectral data. As seen in Fig. 1, a significant difference in the ultraviolet spectrum of the complex was observed at 236 nm when compared to the spectrum of the uncomplexed solution of eosin and methylene blue. This new peak indicated...
the presence of an amide structure in the complex, and it would result from a n → π* transition of the carbonyl group (4).

The occurrence of an amide bond in the dye complex was also indicated by an examination of the infrared spectrum of this compound (Fig. 2). Amides are characterized by a strong absorption in the 1,695 to 1,630 cm⁻¹ region due to C=O stretching (1). The complex exhibited a peak at 1,700 cm⁻¹. Interpretation of this peak as indicating an amide bond was supported by a peak which occurred at 1,275 cm⁻¹. This band would result from a CNH vibration in which the nitrogen and hydrogen atoms moved in the same direction relative to the carbon atom (1). A peak of 640 cm⁻¹ was interpreted as being characteristic of an NH out-of-plane wag whereas a peak at 590 cm⁻¹ was indicative of a C=O out-of-plane bend.

Thus, the formation of the dye complex appeared to be dependent on the pH of the medium and involved formation of an amide bond between eosin and methylene blue, as shown in Fig. 3. The occurrence of this dye complex during growth of E. coli on EMB agar appeared to account for the ability of this medium to differentiate between E. coli and E. aerogenes.
