We describe a new caldoactive bacterium, Dictyoglomus thermophilum, which was isolated from a slightly alkaline hot spring. This organism is a nonsporeforming, nonmotile, obligately anaerobic rod-shaped bacterium that stains gram negative and occurs singly, in pairs, in filaments, and as spherical bodies. The cell surface structure is of the complex gram-negative type. Large spherical bodies are formed by associations of separate rods in numbers ranging from a few to perhaps as many as 100; these spherical bodies are surrounded by common outer wall membrane. The temperature range for growth is between 50 and 80°C, with optimum growth at 78°C; the pH range for growth is between 5.9 and 8.3. The doubling time at 73°C and pH 7.2 is about 2.5 h. Growth is inhibited by streptomycin, tetracycline, neomycin, chloramphenicol, vancomycin, tunicamycin, and sodium dodecyl sulfate. The deoxyribonucleic acid base composition is 29 mol% guanosine plus cytosine. The type strain is strain ATCC 35947.

Bacteria that grow at temperatures over 70°C are called caldoactive or extremely thermophilic (10, 18). It has been pointed out that volcanic environments such as hot springs may be more conducive for the growth of anaerobes than for the growth of aerobes because of the low solubility of O2 at high temperatures, the presence of H2S, and the high organic content associated with decomposing biomass (20). Extremely thermophilic, anaerobic chemoorganotrophs, including Thermoaerobium brockii (20), Thermoanaerobacter ethanolicus (19), and Thermobacteroides acetethylicus (3), have been isolated from hot springs at Yellowstone National Park and from other volcanic environments during the past several years (6, 17, 21–23). We examined hot springs in Japan with the hope of isolating thermophilic anaerobes which may be potentially useful for industrial purposes. One anaerobic isolate is described in this paper. This organism is an extremely thermophilic, nonsporulating, chemoorganotrophic, rod-shaped bacterium which forms large spherical bodies consisting of a few to perhaps 100 separate cells. The properties of this strain do not fit those of any previously described genus.

MATERIALS AND METHODS

Chemicals. All chemicals were reagent grade. Tetracycline and streptomycin sulfate were obtained from Takeda Chemical Industries Ltd., Osaka, Japan. Actinomycin D, d-cycloserine, ampicillin, and vancomycin were obtained from Sigma Chemical Co., St. Louis, Mo; penicillin G was obtained from Meiji Confectionary Co. Ltd., Kawasaki, Japan; neomycin was obtained from Boehringer Mannheim, Mannheim, Federal Republic of Germany, and chloramphenicol was obtained from Sankyo Co. Ltd., Tokyo, Japan. Tunicamycin was a gift from Akira Takatsuki, University of Tokyo, Tokyo, Japan. Lysozyme (6× crystallized) was purchased from Seikagaku Kogyo Co. Ltd., Tokyo, Japan.

Polypeptone, yeast extract, and agar powder were obtained from Takeda Chemical Industries Ltd., Daigoeiyo Chemical Co. Ltd., Osaka, Japan, and Kokusan Chemical Works, Ltd., Tokyo, Japan, respectively. Quetol 812 was provided by Nissin EM Co. Ltd., Tokyo, Japan.

Medium and cultivation conditions. The anaerobic techniques of Hungate (8) were used throughout this study. The anaerobic medium contained (per liter of distilled water) 1.5 g of KH2PO4, 4.2 g of Na2HPO4·12H2O, 0.5 g of NH4Cl, 0.38 g of MgCl2·6H2O, 0.05 g of CaCl2, 0.039 g of Fe(NO3)3·9H2O, 0.1 g of Na2CO3, 2.9 mg of CoCl2·6H2O, 2.4 mg of Na2MoO4·2H2O, 0.17 mg of Na2SeO3, 2.0 mg of MnCl2·4H2O, 2.8 mg of ZnSO4, 2.0 mg of resazurin, 20 μg of biotin, 20 μg of folic acid, 100 μg of pyridoxin hydrochloride, 5 μg of riboflavin, 5 μg of thiamine, 50 μg of nicotinic acid, 50 μg of pantothenic acid, 1 μg of vitamin B12, 50 μg of thiotic acid, 50 μg of p-aminobenzoic acid, 2 g of yeast extract, 2 g of polypeptone, 5 g of soluble starch, and 1.0 g of cysteine hydrochloride. The gas phase in all cultures was nitrogen (1 atmosphere [1.1 × 105 kPa]). The pH of the medium after autoclaving was about 7.2. Vitamins, growth inhibitors (except NaCl and sodium dodecyl sulfate), and antibiotics were sterilized separately by filtration. Cultures were incubated at 73°C unless otherwise stated.

Determination of fermentation products. A glass gas chromatography column (1.0 m by 3 mm) containing 60/80-mesh activated charcoal (Shimadzu Corp., Kyoto, Japan) was used for analysis of H2, CO2, and N2. The column temperature was 75°C, the injection temperature was 120°C, and the detector temperature was 100°C. The carrier gas was helium (flow rate, 30 ml/min). A thermoconductivity detector was used. Ethanol and acetic acid were analyzed with a glass column (1 m by 3 mm) packed with 80/100-mesh Gaskuropak 54 (Gasuroku Kogyo, Inc., Tokyo, Japan). The column temperature was 165°C, and the flame ionization detector temperature was 135°C; helium was the carrier gas (flow rate, 55 ml/min). The same column and detector were used for analysis of volatile acids other than acetic acid; the column temperature was 180°C, the injection temperature was 220°C, and the detector temperature was 220°C. Volatile and nonvolatile acids also were analyzed with a JASCO Tri...
Electron microscopy. Cells grown for 2 days at 73°C were collected by low-speed centrifugation and fixed in 0.01 M cacodylate buffer (pH 7.0) containing 1% glutaraldehyde and 0.15 M NaCl for 1 h. The cells were then dehydrated gradually by washing with increasing concentrations of ethanol and dried by the critical-point method (1). Finally, the samples were dried on grids which were coated with gold-palladium and examined with a model S-430 scanning electron microscope (Hitachi Seisakusho Co. Ltd., Hitachi, Japan). Cells also were fixed by the method of Ryter and Kellenberger (15), with some modifications. Glutaraldehyde (final concentration, 2.5%) was added to 100 ml of a 24-h culture of strain H-6-12\textsuperscript{T} (T = type strain). Cells were collected by centrifugation at 500 \times g for 10 min, suspended in 5 ml of Kellenberger buffer (Veronal acetate buffer containing 0.1 M CaCl\textsubscript{2} at pH 6.1), and centrifuged at 60 \times g for 8 min to remove black mineral precipitates. The cells were resuspended in the same buffer containing 2.5% glutaraldehyde and left at room temperature for 1 h. Then the cells were washed with 8 ml of buffer, suspended in 1 ml of buffer containing 1% osmic acid and 0.1 ml of tryptone medium, and incubated overnight at room temperature. The cells were washed with 8 ml of buffer, suspended in 1 ml of a 2% agar solution (65°C), and immediately centrifuged at 500 \times g.
for 10 min. The solidified agar was cut into 1- to 2-mm cubes. The cubes were placed in 1 ml of buffered 0.5% uranyl acetate for 2 h. The agar blocks were dehydrated by a graded series of water-ethanol mixtures, followed by acetone. They were infiltrated with an acetone-Quetol 812 mixture and embedded in Quetol 812 by incubation at 37°C overnight, at 45°C for 1 day and finally at 60°C for 2 days. Thin sections were cut with model MT-2 ultramicrotome (Ivan Sorvall, Inc., Norwalk, Conn.) and stained with a 3% aqueous uranyl acetate solution, followed by lead citrate, as described by Reynolds (14). Electron microscopy was done with a model JEM JEOL 200 CX electron microscope.

Enrichment and isolation. Water samples containing mud and sediments were collected in 1-liter polyethylene bottles. The tightly capped bottles were kept in a cold room. These samples (20 ml each) were inoculated into 300-ml Erlenmeyer flasks containing 100 ml of medium and incubated anaerobically at 73 to 75°C. The cultures in which visible turbidity developed in 3 to 5 days were transferred to anaerobic culture tubes. After 2 to 3 days of incubation, 10-fold serial dilutions were made and inoculated into medium containing 2.5% molten agar. The agar medium in roll tubes was incubated at 60 to 63°C in a 30° slanted position. The final stock cultures were obtained by selecting well-isolated single colonies. Roll tube culture was repeated several times. Strain H-6-12T was isolated from one of the six water samples collected from Tsuetate Hot Spring (Kumamoto Prefecture, Japan) in February 1982. The temperature and pH of the water were 82°C and 8.7, respectively. Stock cultures of strain H-6-12T were stored under nitrogen at -20°C in 50% glycerol for at least 6 months and by lyophilization.

RESULTS AND DISCUSSION

The cells of strain H-6-12T were gram-negative, nonsporoforming, nonflagellated, obligately anaerobic, long rods that associated to form large spherical bodies. An outer wall membrane was present. The fermentation products were acetate, lactate, and CO2. The G+C content of the DNA was 29 mol%.

These characteristics differ significantly from those of previously described obligately thermophilic, asporogenous, fermentative anaerobes as described below.

Thermoanaerobium brockii is a gram-positive, nonsporoforming, nonmotile, rod-shaped organism that produces lactate, ethanol, acetate, H2, and CO2 as fermentation products. Its DNA base composition is 30 to 31 mol% G+C (20).

Thermoanaerobacter ethanolicus is gram variable (gram positive in the very early logarithmic growth phase) and has peritrichous flagella. It produces ethanol as the main fermentation product and lactate, acetate, H2, and CO2 as minor products. Its DNA base composition is 37 to 38 mol% G+C (19).

Thermobacteroides acetoethylicus is a gram-negative, peritrichously flagellated, nonsporoforming, rod-shaped organism that produces ethanol, acetate, H2, and CO2. Its cell
wall architecture is not typical of gram-positive or gram-negative bacteria. An outer wall membrane, which is common to most gram-negative bacteria, has not been observed. Its DNA base composition is 31 mol% G+C (3).

Strain H-6-12\textsuperscript{T} cannot be identified as a member of any of the genera described above or any other genus described in Bergey's Manual of Determinative Bacteriology and Bergey's Manual of Systematic Bacteriology (5, 9). Therefore, we propose to place strain H-6-12\textsuperscript{T} in a new genus and species, *Dictyoglomus thermophilum* gen. nov., sp. nov., which are described below.

*Dictyoglomus* gen. nov. *Dictyoglomus* (Dic. ty. o. glo' mus; Gr. n. dictyon net; glo' mus L. n. ball; L. n. Dictyoglomus net ball) cells are gram-negative rods with a gram-negative type of cell surface structure, often forming bundles and large spherical bodies. The bundles and large spherical bodies consist of two to several cells and several dozen cells, respectively, and are surrounded by a common outer wall membrane. Nonmotile and nonsporulating. Obligately anaerobic and carbohydrate fermenting. The G+C content of the type species is 29 mol%. The type species is *Dictyoglomus thermophilum*. 

*Dictyoglomus thermophilum* sp. nov. *D. thermophilum* (ther. mo. phil' um; Gr. n. thermus heat; L. adj. philum loving; L. n. thermophilum heat loving) cells are rods that are 0.4 to 0.6 μm wide by 5 to 20 μm long and occur singly, in pairs, in filaments, and in bundles. Several to several dozen cells frequently form large spherical bodies up to 50 to 100 μm in diameter. Gram-negative, nonsporeforming, and nonmotile. Anaerobic; does not grow in an aerobic atmosphere or in a medium in which the color has become light pink due to the oxidation of resazurin by a trace amount of air.

In the late log phase of growth 30 to 50% of the cells are in large bodies (Fig. 1 and 2). Cell aggregates in linear arrays consist of two to several cells and share an outer wall membrane. There seem to be various intermediate forms during growth from single cells to large spherical bodies. The cells may grow and duplicate inside the outer wall membrane. Any excess outer wall membrane produced may be pinched off to form small empty spherical bodies.

Electron microscopic observations indicate that the various types of spherical structures are composed of outer wall membrane. Electron micrographs of ultrathin sections show that the cell surface structure is of the complex gram-negative type (Fig. 3). Flagella are not present. Neither complex membranous structures such as mesosomes nor invaginations of the plasma membrane are observed. The outer layer appears to be a definite membranous structure, no portion of which is connected with the underlying innermost layer. Electron-dense materials are observed between the outer and inner membranes.

Large spherical bodies are formed by association of separate filamentous cells, which are surrounded by a membranous structure (Fig. 4d). This membranous structure is composed of the outer wall membranes which have partially peeled away from the cell surfaces. Figures 4A through C show examples in which two, three and several cells share an outer wall membrane. These forms may be observed as bundles or immature spherical bodies under a light microscope (Fig. 1). There is evidence from electron micrograph sections (Fig. 5) that the large spherical bodies are actually three-dimensional structures of associated cells surrounded by an outer wall membrane.

The cell division profile of strain H-6-12\textsuperscript{T} resembles that of gram-negative bacteria, such as *Escherichia coli* or *Thermus aquaticus* (4). Deep narrow invaginations of the cell envelope are formed (Fig. 6). The cell envelope is tripartite (plasma membrane, thin middle layer, and an outer wall membrane). The bundles and large spherical bodies consist of associated cells surrounded by an outer wall membrane.

Colonies are uniformly round and nonpigmented and grow to a diameter of 2 to 4 mm in 3 to 5 days at 60°C. The optimum temperature range for growth is 73 to 78°C, the maximum temperature is 80°C, and the minimum temperature is 51°C. The doubling time at 77°C in anaerobic culture tubes is about 3.6 h. The doubling times at 73°C in anaerobic culture tubes and minijar fermentors are about 4.3 and 2.5 h (Fig. 7 and 8), respectively.

The optimum pH for growth is about 7; no growth is produced above pH 8.9 or below pH 5.4.

The organism does not grow in media lacking fermentable carbohydrate. The carbohydrates used as energy sources include amygdalin, arabinose, cellobiose, fructose, fucose, galactose, glucose, lactose, maltose, mannotose, melezitose, melibiose, pectin, raffinose, ribose, sucrose, trehalose, xylose, and insoluble starch of potato. Cellulose, merythril, glycerol, t-inositol, mannitol, pyruvate, rhamnose, sorbitol, xylitol, and insoluble starch from corn and wheat are not fermented.
FIG. 4. Cross-sections of 2 (A), 4 (B), 6 (C), and 16 (D) rod-shaped cells which are connected by their outer wall membranes to form a bundle or spherical body. Bars = 0.5 μm.

Strain H-6-12<sup>T</sup> ferments 0.5% soluble starch to produce 16 mM acetate, 3 mM lactate, about 12 mM CO<sub>2</sub>, and trace amounts of H<sub>2</sub>.

A very heat stable α-amylase is produced. The methyl red test, indole production, and nitrate reduction are negative. The Voges-Proskauer test is positive. Catalase activity is not detected.

Growth is inhibited by 10 μg of streptomycin per ml, 10 μg of tetracycline per ml, 100 μg of chloramphenicol per ml, 10 μg of neomycin per ml, 100 μg of vancomycin per ml, 100 μg of actinomycin D per ml, 10 μg of tunicamycin per ml, 2% sodium chloride, and 100 μg of sodium dodecyl sulfate per ml.

Cells are resistant to lysozyme and lysozyme plus ethylenediaminetetraacetate. Incubation of cells in 50 mM tris (hydroxymethyl) aminomethane hydrochloride buffer (pH 7.6) containing 78 μg of lysozyme per ml and 1 mM ethylenediaminetetraacetate for 20 min at 37°C causes no decrease in absorbance at 550 nm of a cell suspension. However, light microscope observations reveal the appearance of partial extrusions like protoplast structures from some long cells. After incubation the cells are lysed by the addition of 1% sodium dodecyl sulfate, whereas the addition of the same concentration of sodium dodecyl sulfate does not lyse untreated cells. The large spherical bodies are rapidly decomposed to separate filamentous cells by the addition of 0.1% sodium dodecyl sulfate, whereupon each cell become thinner.

Isolated from slightly alkaline hot springs (Tsuetate Hot Spring) in Kumamoto Prefecture, Japan. The DNA base composition is 29 mol% G+C.

HoloType strain: Dictyoglomus thermophilum H-6-12 (= ATCC 35947).

Brock and Edwards reported the production of similar
large spherical bodies, which they called rotund bodies, by an aerobic extreme thermophile, *Thermus aquaticus* (4). In *Thermus aquaticus*, *Escherichia coli* (2), and *Thiobacillus thiooxidans* (12) portions of the outer wall membrane are connected to the underlying innermost layer. In *D. thermophilum* connections between the outer wall layer and the underlying innermost layer cannot be seen. This apparent lack of the connection may allow easy peeling of the
