Two strains of thermophilic photosynthetic bacteria, designated MD-66T (T = type strain) and YI-9, were isolated from bacterial mats in two separate hot springs in Japan. These new isolates were phenotypically similar to Chloroflexus aurantiacus in some respects. They were thermophilic filamentous photosynthetic bacteria that grew well at 55°C either anaerobically as phototrophic or aerobically as chemoheterotrophs. They exhibited gliding motility, produced bacteriochlorophylls a and c, contained chlorosomes, and required thiamine and folic acid as growth factors. However, isolates MD-66T and YI-9 had the ability to rapidly form mat-like dense aggregates of filaments, an ability which has not been observed in any C. aurantiacus strain. Carbon source utilization tests revealed that unlike C. aurantiacus, the new isolates did not utilize acetate, citrate, ethanol, or glycerglycine. An analysis of the carotenoid components revealed that isolates MD-66T and YI-9 contained mainly γ-carotene and OH-γ-carotene glucoside fatty acid esters. These isolates also contained only trace amounts of β-carotene, which is a major carotenoid component (28.4% of the total carotenoids) in C. aurantiacus. The results of DNA hybridization studies suggested that the new strains were genetically distinct from C. aurantiacus (levels of similarity, 9 to 18%), and 16S rRNA sequence comparisons showed that strain MD-66T was related to C. aurantiacus at a similarity level of 92.8%. On the basis of our data, we propose that a new Chloroflexus species should be created for our new isolates; the name of this new species is Chloroflexus aggregans, and the type strain is strain MD-66 (= DSM 9485).

The first filamentous anoxygenic phototrophic bacteria were discovered by Pierson and Castenholz in thermophilic environments (25). These organisms were described as members of a new genus and species, Chloroflexus aurantiacus, and strain J-10-T, which was isolated from a Japanese hot spring, was designated the type strain of this species (26). Following this description, Gorlenko and coworkers found members of two apparently related mesophilic filamentous phototrophic genera in freshwater habitats, the genera Chloronema (4) and “Oscillochloris” (9). These organisms exhibited gliding motility and contained pigment-bearing vesicles called “chlorosomes” (32). The group containing the phototrophic bacteria includes representatives of another genus, the genus Heliothrix, as described by Pierson et al. (29). Members of the genus Heliothrix have not been isolated in pure culture yet, but they are known to lack chlorosomes. The results of a 5S rRNA sequence analysis showed that Heliothrix oregonensis is phylogenetically related to Chloroflexus aurantiacus.

A phylogenetic analysis based on 16S rRNA sequence data revealed that Chloroflexus aurantiacus is not closely related to any other phototrophic bacteria and forms a remarkably deep branch on the common line of eubacterial descent (23). Consequently, the filamentous phototrophs are now placed in a group called the “multicellular filamentous green bacteria” (24, 36) or the “filamentous anoxygenic phototrophs” (27).

Chloroflexus strains and their relatives have been detected and observed in hot springs, freshwater lakes, and marine environments (1–3, 7, 8, 16, 19, 30, 33, 34). However, most strains have not been isolated in axenic culture, and molecular phylogenetic data are not available for any organisms except Chloroflexus aurantiacus, Heliothrix oregonensis, and the recently described isolate Oscillochloris trichoides DG-6 (16, 26, 29).

We isolated several strains of thermophilic filamentous phototrophic bacteria from various hot springs in Japan by using an improved isolation method (11). Most of these new isolates were assigned to C. aurantiacus on the basis of morphological, physiological, and chemotaxonomic characteristics and DNA-DNA hybridization data. However, two of the isolates, designated MD-66T (T = type strain) and YI-9, clearly differed from Chloroflexus aurantiacus in that they formed mat-like dense aggregates. The results of a preliminary DNA-DNA hybridization assay suggested that there is a distinct genetic distance between these two isolates and Chloroflexus aurantiacus.

In this study, we characterized these aggregate-forming strains by determining their morphological, physiological, and genetic properties. We found that the new strains represent a distinct species of the genus Chloroflexus, and we propose the name Chloroflexus aggregans sp. nov. for this taxon.

MATERIALS AND METHODS

Bacterial strains and growth conditions. Strain MD-66T (= DSM 9485) was isolated from bacterial mats in an outflow (57°C, pH 7.0) of the Ooki Onsen hot spring in Tochigi Prefecture, Japan. This spring contains sodium chloride (18 mM) and sodium bicarbonate (3 mM) as its major salts and trace amounts of sulfide, and the bacterial mat consisted of a dark green layer of filamentous and unicellular cyanobacteria covered with bright yellow streamers (length, approximately 1 cm) that were composed of filamentous green bacteria. Strain YI-9 (= DSM 9406) was isolated from the Yufuin hot spring (67°C, pH 8.2) in Oita Prefecture, Japan. These strains were isolated by using PE medium supplemented with 1.5% agar. This medium contained (per liter) 0.5 g of sodium glutamate, 0.5 g of sodium succinate, 0.5 g of sodium acetate, 0.5 g of yeast extract (Difco), 0.5 g of Casamino Acids (Difco), 0.5 g of Na2SO4·H2O, 0.38 g of KH2PO4, 0.39 g of K2HPO4, 0.5 g of (NH4)2SO4, 1 ml of a vitamin mixture, and 5 ml of a basal salt solution. The pH of the medium was adjusted to 7.5 with NaOH. The vitamin mixture contained (per 100 ml) 100 mg of

nictic acid, 100 mg of thiamine hydrochloride, 5 mg of biotin, 50 mg of p-aminobenzoic acid, 1 mg of vitamin B12, 50 mg of calcium pantothenate, 50 mg of pyridoxine hydrochloride, and 50 mg of folic acid. The basal salt solution contained (per liter) 1.11 g of FeSO₄·7H₂O, 2.465 g of MgSO₄·7H₂O, 2.94 g of CaCl₂·2H₂O, 0.24 g of K₂HPO₄, 0.049 g of Na₂HPO₄·2H₂O, 0.005 g of MgCl₂·6H₂O, 28.98 mg of ZnSO₄·7H₂O, 2.92 mg of Co(NO₃)₂·6H₂O, 25.2 mg of CuSO₄·5H₂O, 24.2 mg of Na₂MoO₄·2H₂O, 31.0 mg of H₃BO₃, and 4.53 g of trisodium EDTA. Enrichment cultures were established by using the same medium and were incubated in screw-cap tubes or bottles at 55°C under anaerobic incubation light (approximately 30 W/m²) (11).

Electron microscopy. Phototrophically grown cells were harvested and embedded in 2% agar (27). The agar was cut into 1-mm cubes and fixed for 4 h at room temperature with 2.5% glutaraldehyde in Kellenberger buffer (pH 6.8) supplemented with 0.05% ruthenium red (15, 18). The cubes were washed and postfixed with 1% OsO₄ in buffer containing 0.05% ruthenium red at 4°C for 6 h. They were then washed again and placed in 0.5% uranyl acetate in water for 1 h at room temperature. After washing and dehydration, the cubes were embedded in Spurr embedding medium (17). Thin sections were stained with 5% uranyl acetate at 20 min at 45°C and with 0.002% lead citrate for 1 min at room temperature (37). Micrographs were taken with a JEOL model JEM-1010 electron microscope operating at 80 kV.

Physiological tests. For nutritional experiments we used the media used for Chloroflexus aurantiacus, as previously described by Madigan et al. (21), with some modifications. The basic medium contained (per liter) 0.38 g of KH₂PO₄, 0.39 g of K₂HPO₄, 0.5 g of Na₂HPO₄·7H₂O, 0.5 g of (NH₄)₂SO₄, 1 ml of the vitamin mixture, and 5 ml of the basal salt solution (see above). The final pH of the medium was adjusted to 7.5. For each nutritional test performed under aerobic conditions, we used 5 ml of autoclaved basic medium containing an organic carbon source at a final concentration of 0.25% (wt/vol) in a 30-ml L-shaped tube closed with a silicon sponge stopper; the tubes were incubated under aerobic conditions in the dark at 55°C. For each nutritional test performed under anaerobic conditions, we used a 30-ml screw-cap tube filled with basic medium supplemented with a filter-sterilized sulfide-bicarbonate solution (Na₂S·9H₂O at a final concentration of 0.05% [wt/vol], NaHCO₃ at a concentration of 0.03% [wt/vol]) and an organic carbon source at a concentration of 0.25% (wt/vol); the tubes were incubated in the light or in the dark at 55°C. All organic carbon sources were neutralized and sterilized before they were added. Vitamin requirements were determined by using eight vitamin combinations, each of which lacked one of eight vitamins (nicotinic acid, thiamine hydrochloride, biotin, p-aminobenzoic acid, vitamin B₁₂, calcium pantothenate, pyridoxine hydrochloride, folic acid). An organic medium containing 2% vitamin-free Casamino Acids (Difco) was used in this test, and the final results were determined after three serial transfers.

Spectroscopy and pigment analyses. Cells were collected from 2-day cultures in PE medium and then were washed and disrupted by sonication at 140 W for 5 min in MOPS-potassium-magnesium buffer (0.01 M MOPS [morpholinepropane sulfonic acid]-NaOH, 0.1 M KCl, 0.001 M MgCl₂; pH 7.0). The absorption spectra of ultrasonically disrupted cells in buffer were determined with a Shimadzu model UV-160 spectrophotometer. Pigments were extracted with chloroform-methanol (3:1, vol/vol) and were analyzed by reverse-phase high-performance liquid chromatography (HPLC) by using methanol as the solvent (35).

Genetic properties. Genomic DNA was purified by the method of Marmur (22). The guanine-plus-cytosine (G+C) content was determined by performing DNA-DNA hybridization experiments with genomes of known base composition (27). The G+C content of some isolates was 57 mol%. Septa were distinguished, and the lengths of individual septa in filaments were measured directly by the cycle sequencing method modified for automated fluorescence detection (12, 14).

RESULTS

Morphology. The cells of the cluster-forming strains formed unbranched multicellular filaments of indefinite length. The diameters of full-grown filaments ranged from 1.0 to 1.5 μm (Fig. 1). Septa were observed with a phase-contrast microscope, and the lengths of the individual cells in the filaments ranged from 2 to 6 μm. Granular inclusions were found commonly.

Electron microscopic observations of ultrathin sections (Fig. 2a) showed that the cells of strain MD-66T were 0.5 to 0.6 μm wide. Septa were distinguished, and the lengths of individual cells ranged from 2 to 5 μm. Vesicular structures, presumably chlorosomes, were observed along the cytoplasmic membrane in the cytoplasm. No sheaths were observed (Fig. 2b).

Photosynthetic pigments. The cells of strains MD-66T and YI-9 were green or greenish brown when the organisms were grown phototrophically in PE medium. Ultrasonically disrupted cells in buffer had absorption maxima at 464, 740, 803, and 868 nm, and a shoulder at around 510 nm (Fig. 3), which indicates that carotenoids and bacteriochlorophylls a and e were present. This spectrum resembles that of Chloroflexus aurantiacus. An HPLC analysis revealed that the carotenoid components of the new isolates were mainly γ-carotene and OH-γ-carotene glycoside fatty acid esters and that there was a trace amount of β-carotene (data not shown). When grown anaerobically in 5-ml portions of PE medium in 30-ml L-shaped tubes shaken vigorously in the dark, the cells of the new isolates were reddish brown or orange because of the production of carotenoids and small amounts of bacteriochlorophylls even in the early log phase. The concentration of bacteriochlorophyll c was approximately 0.5 nM when the optical density at 620 nm of an aerobic culture of one of the new isolates was 0.05. Under parallel conditions cultures of Chloroflexus aurantiacus J-10T were light pink in the early log phase because of the presence of small amounts of carotenoids and no bacteriochlorophyll (no bacteriochlorophyll c was detected when the optical density at 620 nm of the culture was 0.05), as described previously by Fuller and Redlinger (6).

Active cell aggregation. When strain MD-66T cells were grown with illumination, they formed mat-like dense aggregates that appeared to be “green balls” (Fig. 4). Aggregation was observed within 20 to 30 min each time that the cells were dispersed by shaking. The most rapid aggregation occurred at temperatures around 55°C, which was the optimum temperature for growth of this organism. Since the aggregation that occurred was dependent on illumination or the oxygen supply, it could be considered active aggregation. This aggregation was probably due to the gliding motility of the filaments, which was
HAVE LENGTH (nm)

FIG. 3. Absorption spectrum obtained with strain MD-66T cells grown under anaerobic conditions in the light in PE medium. The cells were ultrasonically disrupted in MOPS-sodium-magnesium buffer.

observed on the surface of a glass slide under a microscope, and the maximum rate was 1 to 3 μm/s at 55°C. Details about the motility of Chloroflexus aggregans and the formation of mat-like dense aggregates by this organism will be described elsewhere.

**Physiological and other characteristics.** Strains MD-66T and YI-9 were able to grow either anaerobically as photoheterotrophs or aerobically as chemoheterotrophs, like Chloroflexus aurantiacus. These strains grew at pH values ranging from 7.0 to 9.0. The optimum temperature for growth was between 50 and 60°C. Both strains required thiamine and folic acid as growth factors. Table 1 shows the carbon sources utilized by these strains. Under anaerobic, light conditions, both strains utilized a wide variety of organic substrates. The highest growth rates and greatest cell yields were obtained in media containing yeast extract or Casamino Acids as the carbon source. In contrast, strains MD-66T and YI-9 did not utilize most simple organic compounds as carbon sources under aerobic, dark conditions. Only yeast extract and Casamino Acids supported growth under aerobic conditions. Under anaerobic conditions in the dark, none of the substrates tested supported growth. Photoautotrophic growth with sulfide or thiosulfate as the electron donor was not observed with either strain.

**Genetic properties.** The DNA base compositions of the new isolates as determined by HPLC were 56.7 to 57.0 mol% G+C. These values are 2 to 3% higher than the values reported previously for Chloroflexus aurantiacus strains (26). The previously published values, however, were determined by the buoyant density method. Therefore, we determined the G+C base
were determined by direct automated sequencing. The sequence of the entire 16s rRNA gene. The 16s rRNA sequence of strain MD-66T and YI-9 was approximately 80%, while the levels of homology between the new strains and *Chloroflexus aurantiacus* were comparable to that obtained with yeast extract or was significantly less than that obtained with yeast extract (+). –, carbon source did not support growth. Faint growth was observed. Initial growth occurred, but sustained growth was not observed.

**DISCUSSION**

Our new isolates, strains MD-66T and YI-9, are thermophilic, filamentous, phototrophic bacteria which grow well at 55°C either anaerobically as photoheterotrophs or aerobically as chemoheterotrophs and inhabit freshwater hot springs. These organisms exhibit gliding motility, produce bacteriochlorophylls a and c, contain chlorosomes, and require thiamine and folic acid as growth factors. In these respects, the new strains are similar to *Chloroflexus aurantiacus* (20, 26).

However, our data revealed marked phenotypic differences between the new strains and *Chloroflexus aurantiacus*. The most distinctive property of the new organisms is their ability to rapidly form mat-like dense cell aggregates. Whenever aggregated cells were dispersed by shaking, dense aggregates formed again within 20 to 30 min, with the energy required supplied by photosynthesis or respiration. *Chloroflexus aurantiacus* OK-70-fl tends to aggregate in tubes containing liquid medium under anaerobic conditions, but this aggregate formation is not rapid, unlike that observed with the new isolates. The rapid aggregation which we observed seemed to be linked to the fast gliding rate of the cells, which was determined on the surface of a glass slide with a microscope; the maximum gliding rate was 1 to 3 µm/s at 55°C. The gliding rate of the new isolates is approximately 100 times higher than the gliding rates of *Chloroflexus aurantiacus* strains (the gliding rates of strain J-10-fl¹ filaments on 1.5% agar were 0.01 to 0.04 µm/s) and 10 times higher than the gliding rates of *Heliothrix oregonensis* F-1, which also forms clumps rapidly and has gliding rates of 0.1 to 0.4 µm/s (26, 28).

Morphologically, the new isolates form unbranched multicellular filaments of indefinite length, like *Chloroflexus aurantiacus*. However, the cells of the new isolates are significantly wider than the cells of the type strain of *Chloroflexus aurantiacus* (J-10-fl) and slightly wider than the cells of strain OK-70-fl. The carbon source utilization tests revealed that unlike *Chloroflexus aurantiacus* (21), the new isolates do not utilize acetate, citrate, ethanol, or glycolglycine. Our analysis of carotenoid components revealed that the new isolates contain mainly γ-carotene and its derivatives, as well as trace amounts of β-carotene, while β-carotene is a major carotenoid component (28.4% of the total carotenoids) in *Chloroflexus aurantiacus* (10). In addition, the quinone compositions of the new isolates and *Chloroflexus aurantiacus* differed, as the new isolates produced a small but significant amount of menaquinone 4 in addition to the predominant homolog, menaquinone 10 (11).

The G+C contents of the DNAs of the new isolates are 56.7 to 57.0 mol%, values which are similar to the values obtained for *Chloroflexus aurantiacus* J-10-fl¹ and OK-70-fl (56.9 and

\textsuperscript{b} Every site with a gap in any sequence was excluded from the analysis. The value for sequences that were different at every site was 1; all values were normalized to this value.

57.1 mol\%, respectively). However, the levels of genomic DNA hybridization between the new isolates and \textit{Chloroflexus aurantiacus} are low (range, 9 to 18\%), which suggests that these organisms are not conspecific. In view of the phenotypic and genotypic data presented above, it is reasonable to conclude that our isolates should be classified as members of a new species of filamentous green bacteria. The remaining problem is the taxonomic relationship of the new isolates to \textit{Chloroflexus aurantiacus} at the generic level. 16S RNA gene sequence comparisons showed that the level of sequence similarity between strain MD-66\textsuperscript{b} and \textit{Chloroflexus aurantiacus} is 92.8\%, which seems to be low enough to warrant placement in different genera from a phylogenetic viewpoint. However, we believe that at this time it is appropriate to classify the new isolates as members of a new \textit{Chloroflexus} species, because there are only a few phenotypic properties that could be used for generic separation.

On the basis of our phenotypic, genotypic, and phylogenetic data, we classify the new strains as members of a new \textit{Chloroflexus} species, for which we propose the name \textit{Chloroflexus aggregans} sp. nov.

\textbf{Description of \textit{Chloroflexus aggregans} sp. nov.} \textit{Chloroflexus aggregans} (ag'gre'gans. L. v. aggregare, to flock or band together, L. pres. part. aggregates, assembling, aggregating). Cells form unbranched multicellular filaments of indefinite length. The filaments are clearly septate. The diameters of cells range from 1.0 to 1.5 \(\mu\text{m}\). Cells have no flagella but are motile by gliding. Gram negative. Cultures grow by forming mat-like aggregates in liquid that have the appearance of green balls. Cell aggregates reform rapidly whenever a culture is shaken to produce a uniform suspension under growth conditions. Photosynthetic cultures are green to greenish brown. Bacteriochlorophylls \(a\) and \(c\) are present in phototrophically grown cells (under anaerobic conditions) and to a certain extent in chemotrophically grown cells under aerobic conditions. Chlorosomes are present. The major carotenoid components are \(\gamma\)-carotene and \(\alpha\)-\(\gamma\)-carotene glycoside fatty acid esters; there is also a trace amount of \(\beta\)-carotene.

Thermophilic facultative phototrophs that grow optimally at 55°C. Aerobic growth in the dark occurs at full atmospheric oxygen tension. Thiamine and folic acid are required as growth factors. Good carbon sources are yeast extract and Casamino Acids. Simple organic compounds such as intermediates of the citric acid cycle, glutamate, and aspartate are utilized as sole carbon sources only under phototrophic conditions. The major quinone is menaquinone 10. A trace amount of menaquinone 4 is also present.

Habitat: bacterial mats with cyanobacteria in freshwater of hot springs (50 to 67°C).

The G+C content of the DNA is 56.7 to 57.0 mol\% (as determined by the HPLC method).

The type strain is strain MD-66 (= DSM 9485).
