Rhodopseudomonas rhenobacensis sp. nov.,
a new nitrate-reducing purple non-sulfur bacterium

INTRODUCTION

The purple non-sulfur bacteria are a versatile group of bacteria that grow anaerobically in the light or aerobically in the dark with different carbon sources, electron donors and nitrogen sources. The capacity to reduce nitrate, either for assimilatory or dissimilatory growth, is not a common feature of this group of bacteria, being restricted to several species. Due to the fact that most work concerning nitrate reduction in purple non-sulfur bacteria is done with Rhodobacter capsulatus and Rhodobacter sphaeroides, we were interested in isolating nitrate-reducing strains not belonging to these two species.

In the course of isolating and identifying nitrate-reducing purple non-sulfur bacteria we have isolated several strains from eutrophic ponds in the vicinity of Bonn, Germany. One of these strains, belonging to the species Rhodoferax fermentans, was described earlier (Hougardy & Klemme, 1995). In this paper, genotypic and phenotypic characteristics of another isolate are described. We conclude that it should be classified as a new species of the genus Rhodopseudomonas, for which we propose the name Rhodopseudomonas rhenobacensis.
the same composition as before. Pure cultures were achieved by repeated restreaking on agar plates.

Bacterial strains and cultivation. Of 42 isolates one (strain Rb) was used for further investigation. *Rhodopseudomonas palustris* DSM 123¹ was used for comparison. All strains were routinely cultivated under photosynthetic conditions (28 °C, illuminated at 60 W by tungsten lamps at a distance of 20 cm) using the RCV medium described by Weaver et al. (1975) supplemented with 0.05% yeast extract instead of thiamin. In minimal media, yeast extract was replaced by a vitamin solution (Imhoff & Trüper, 1991). Aerobic dark cultivation (28 °C) was performed in Erlenmeyer flasks filled to only 10% of their volume and agitated on a shaker.

Phenotypic characterization. Light-microscopic observations were performed using a ZEISS Axioshot microscope (Carl Zeiss). Electron micrographs for visualization of flagella and intracytoplasmic membranes (ICMs) were kindly provided by Professor Ulrich Fischer (University of Bremen, Germany). Absorption spectra were measured according to the method of Biebl & Drews (1969). Carbon-source utilization tests were performed in screw-cap tubes containing mineral base medium supplemented with the neutralized, filter-sterilized organic compound (final concentration 20 mM) as the carbon source. In growth experiments with butyrate as the carbon source, malate was replaced by 10 mM butyrate and KHCO₃ (30 mM) was added from filter-sterilized stock solutions. In all growth-response tests, growth was monitored turbidometrically at 650 nm. Test tubes in which the OD₆₅₀ after 6 d was greater than the OD₆₅₀ of a negative control containing no test substrate were considered positive for growth. NO₃ in the culture fluids was determined, after removal of bacterial cells by centrifugation, by colorimetric techniques (Nicholas & Nason, 1957).

Extraction of respiratory lipoquinones and polar lipids. Respiratory lipoquinones and polar lipids were extracted from 100 mg freeze-dried cell material using the two-stage method described by Tindall (1990a, b). Respiratory quinones were extracted using methanol/hexane (Tindall, 1990a, b) and the polar lipids were extracted by adjusting the remaining methanol/0.3% aqueous NaCl phase (containing the cell debris) to give a chloroform/methanol/0.3% aqueous NaCl mixture (1:2:0.8, by vol.). The extraction solvent was stirred overnight and the cell debris pelleted by centrifugation. Polar lipids were recovered into the chloroform phase by adjusting the chloroform/methanol/0.3% aqueous NaCl mixture to a ratio of 1:1.09 (by vol.).

Analysis of respiratory lipoquinones. Respiratory lipoquinones were separated into their different classes (menaquinones and ubiquinones) by TLC on silica gel (Macherey-Nagel), using hexane/tert-butylmethylether (9:1, v/v) as solvent. UV-absorbing bands corresponding to menaquinones or ubiquinones were removed from the plate and further analysed by HPLC. This step was carried out on a reverse-phase column (Macherey-Nagel; RP18; 2 mm × 125 mm, 3 µm particle size) using methanol as the eluant. Respective lipoquinones were detected at 269 nm.

Analysis of polar lipids. Polar lipids were separated by two-dimensional silica gel TLC (Macherey-Nagel). The first direction was developed in chloroform/methanol/water (65:25:4, by vol.) and the second in chloroform/methanol/acetic acid/water (80:12:15:4, by vol.). Total lipid material and specific functional groups were detected using 5% dodecylmolybdophosphoric acid (total lipids), Zinzadze reagent (phosphate), ninhydrin (free amino groups), periodate-Schiff (α-glycols), Dragendorff (quaternary nitrogen) and anisaldehyde/sulphuric acid (glycolipids) (Stahl, 1967).

Fatty acid analysis. Fatty acids were analysed as the methyl ester derivatives prepared from 10 mg dry cell material. Cells were subjected to differential hydrolysis in order to detect ester-linked and non-ester-linked (amide bound) fatty acids (B. J. Tindall, unpublished). Fatty acid methyl esters were analysed by GC using a 0.3 μm × 25 m non-polar capillary column and flame ionization detection. The run conditions were: injection and detector port temperature 300 °C, inlet pressure 60 kPa, split ratio 50:1, injection volume 1 μl, with a temperature program from 130 to 310 °C at a rate of 4 °C min⁻¹.

The unambiguous position of double bonds and the presence of hydroxy fatty acids was confirmed by GC-MS. Hydroxy fatty acids were detected by their characteristic fragments at m/z 103 for 3-OH fatty acids, and at m/z M⁻ – 59 for 2-0H fatty acids. The position of double bonds was determined using dimethyl disulphide adducts as described by Nichols et al. (1986).

GC-MS. GC-MS analysis of the fatty acids was carried out using a Finnigan MAT GCQ gas chromatograph-mass spectrometer. The gas chromatograph was equipped with a DB-5 column (30 m × 0.22 mm, film thickness 0.25 µm), and helium, at a linear velocity of 40 cm s⁻¹, was used as the carrier gas. Samples (1 μl) were injected in the splitless mode and separated using a temperature programme starting at 80 °C (held for 1 min.) followed by a rise of 10 °C min⁻¹ to 300 °C. The mass spectrometer was run in the EI mode, with a source temperature of 175 °C and a transfer line temperature of 275 °C. Samples were run either without derivatization or as the dimethyl disulphide derivatives for detecting the position of double bonds.

DNA base composition and DNA–DNA hybridization. DNA was isolated according to the method described by Viswanathan (1989) and by chromatography on hydroxyapatite by the procedure of Cashon et al. (1977). The G+C content of the DNA was determined by HPLC. DNA–DNA hybridization was carried out according to the method of De Ley et al. (1970) using a Gilford System 2600 spectrophotometer equipped with a Gilford 2527-R thermoprogrammer and plotter. These analyses were conducted by the DSMZ, Braunschweig, Germany.

16S rDNA sequencing and phylogenetic analysis. 16S rDNA fragments that correspond to positions 8–1401 of *Escherichia coli* were amplified by PCR from chromosomal DNA and sequenced using the 536f and 515r primers by the primer-extension method. The reactions were analysed with a Pharmacia automated laser fluorescent DNA sequencer (analyses conducted by Werner Arnold, University of Bielefeld, Germany).

The CLUSTAL W program (Thompson et al., 1994) was used for multiple alignment, calculation of evolutionary distance, construction of a neighbour-joining phylogenetic tree and statistical evaluation of the tree topology by bootstrap analysis. Alignment positions including gaps and/or unidentified bases (approx. 7%) were not taken into consideration for the calculations.

Nucleotide sequence accession numbers. The accession numbers for the sequences used to construct the distance matrix tree are as follows: Bradyrhizobium elkanii, AF081266; Bradyrhizobium japonicum, X66024; Nitrobacter.
Rhodopseudomonas rhenobacensis sp. nov.

RESULTS

Isolation

We attempted to enrich nitrate-reducing purple non-sulfur bacteria other than *Rhodobacter capsulatus* or *Rhodobacter sphaeroides*. To avoid the selection of these fast-growing *Rhodobacter* species, the medium used for enrichment was supplemented with 0.5 mM EDTA, since most strains of the latter two species are strongly inhibited by EDTA at this concentration (Kern *et al.*, 1992). We successfully isolated 42 strains of purple non-sulfur bacteria. One isolate, strain RbT, which was isolated from a eutrophic pond located in the forest of Rheinbach, Germany, is described in this paper.

Morphology and ultrastructure

Strain RbT had rod-shaped cells that tend to form rosette-like clusters in older cultures as described for *Rhodopseudomonas palustris* and *Rhodopseudomonas viridis*. The cells measured 0.4–0.6 μm in width and 1.5–2.0 μm in length, and were motile by means of a single polar flagellum (Fig. 1). Cell division occurred by budding. Electron microscopy of ultrathin sections revealed the presence of internal membranes of the lamellar type. The cell morphology and ultrastructure are shown in Fig. 2.

Photopigments

The colour of photosynthetically grown liquid cultures of strain RbT was dark red. Absorption maxima of cell homogenates were at 376, 471, 503, 540, 591, 805 and 878 nm (Fig. 3), indicating the presence of bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin series. Cultures grown aerobically in the dark were colourless.

Physiological characteristics

Strain RbT was able to grow anaerobically in the light or aerobically in the dark. The following organic compounds served as carbon sources: formate, acetate, butyrate, pyruvate, lactate, malate, succinate, fumarate, tartrate, gluconate and ethanol. No growth occurred with citrate, benzoate, propionate, glucose, fructose and methanol (Table 1). Ammonium, yeast extract, glutamate and molecular nitrogen were used as sole nitrogen sources. Nitrate was reduced to nitrite, which accumulated in the medium. The utilization of thiosulfate was not possible. The pH range for growth was 5.0–8.0 with a pH optimum of 5.5. Growth was completely inhibited by 1% (w/v) NaCl. *p*-Aminobenzoic acid was required as a growth factor, but could be replaced by 0.05% yeast extract. Gelatin was not hydrolysed.

Quinones and fatty acids

Examination of the respiratory lipoquinone content of strain RbT indicated that only ubiquinones were present, and the predominant compound present was ubiquinone 10. These findings are consistent with the placement of this organism in the α-subclass of the *Proteobacteria* (Yokota *et al.*, 1992; Collins & Jones, 1981; B. J. Tindall, unpublished). The predominant fatty acid was 18:1ω7c, accounting for more than 60% of the total fatty acids present. The predominance of this fatty acid is also a characteristic feature of members of the α-subclass of the *Proteobacteria*. Differentiation of strain RbT from other taxa and its assignment to the genus *Rhodopseudomonas* was confirmed by the presence of smaller amounts of 16:0, 18:0, 16:1ω7c, together with 3-OH 14:0 (Table 2). The latter fatty acid was exclusively non-ester linked and is probably amide linked to the lipopolysaccharide, as is the case in *Rhodopseudomonas palustris* (Weckesser & Mayer, 1988). The polar lipids comprised phosphatidyl glycerol, phosphatidyl glycerol, phosphatidyl ethanolamine, phosphatidyl

choline and an amino lipid which also stained periodate–Schiff positive. This compound was stable towards both acid and alkali, and was tentatively identified as an amino hopanoid, which has been reported in *Rhodopseudomonas palustris* (Neunlist *et al*., 1988), and was detected in the polar lipid fraction of *Rhodopseudomonas palustris*, with the same \(R_f\) value. This polar lipid pattern is characteristic for all members of the *Bradyrhizobium–Nitrobacter–Afipia–Rhodopseudomonas* phyletic group examined to date (B. J. Tindall, unpublished; Moss *et al*., 1990; Brenner *et al*., 1991).

DNA base composition

The G+C content of the DNA of strain Rb\(^{+}\) was 65·4±0·2 mol\%, which is similar to that of *Rhodopseudomonas palustris* and *Rhodopseudomonas*
The sequence of two fragments of the 16S rRNA gene from strain Rb\textsuperscript{T} was compared with the sequences from representative species of phototrophs and their non-phototrophic relatives of the α-subclass of the Proteobacteria. Strain Rb\textsuperscript{T} was closely related to *Bradyrhizobium japonicum*, *Nitrobacter winogradskyi* and *Rhodopseudomonas palustris* at a similarity level of 96–98\% but showed much lower affinities to all other members of the purple non-sulfur bacteria (< 93\% similarity, data not shown). On the basis of the corrected distance values a neighbour-joining tree was constructed (Fig. 4). Strain Rb\textsuperscript{T}, *Rhodopseudomonas palustris*, *Bradyrhizobium japonicum* and *N. winogradskyi* formed a tight cluster distinct from *Rhodopseudomonas acidophila* and all other purple non-sulfur bacteria investigated. The monophyletic nature of this cluster was supported by bootstrapping in 100\% of the 1000 trees generated. The level of DNA–DNA hybridization with the only other purple non-sulfur bacterium in this cluster, *Rhodopseudomonas palustris* DSM 123, was 37–5\%. This low level of genomic DNA relatedness supports the differentiation of the two strains at the species level, supporting the results of the physiological tests.

*acidophila* and slightly higher than the G + C content of *Rhodopseudomonas julia* (63.5 mol%).

**Genetic relationships**

The sequence of two fragments of the 16S rRNA gene from strain Rb\textsuperscript{T} corresponding to position 36–487 and 566–1236, respectively (*E. coli* numbering), was determined. The deduced 16S rRNA molecule exhibited nucleotide deletions of 11 bases in the loop structure at position 201–215. This feature is characteristic for species belonging to the α-subclass of the Proteobacteria (Woese, 1987). The sequence of strain Rb\textsuperscript{T} was compared with the sequences from representative species of phototrophs and their non-phototrophic relatives of the α-subclass of the Proteobacteria. Strain Rb\textsuperscript{T}
DISCUSSION

In recent years the unsatisfactory taxonomy of the genus *Rhodopseudomonas* was clarified on the basis of 16S rRNA sequence analysis, and phenotypic and chemotaxonomic data. The consequence was that a number of new genera, like *Rhodobium*, *Blastochloris* and *Rhodoplanes* (Hiraishi & Ueda, 1994; Hiraishi et al., 1995) were created. It was suggested by Hiraishi (1997) that only the type species *Rhodopseudomonas palustris* should remain in the genus *Rhodopseudomonas*. To date the genus *Rhodopseudomonas* comprises the species *Rhodopseudomonas palustris*, *Rhodopseudomonas acidophila* and *Rhodopseudomonas julia*.

The results of our experiments show that the new isolate is facultatively photoheterotrophic, multiplies by budding and possesses ICM of the lamellar type with bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. Among species with these features our isolate resembles most closely *Rhodopseudomonas palustris*. However, a characteristic feature of *Rhodopseudomonas palustris*, the utilization of benzoate, is not shown by our isolate. The optimum pH for growth also differs between the two strains. The inability of strain Rb*T* to utilize benzoate could be due to the lack of only a few enzymes, but the optimal growth at pH 5-5 seems to be a more complex feature. Our isolate resembles *Rhodopseudomonas acidophila* with respect to the optimum pH for growth, but differs in size, vitamin requirement and carbon utilization. The 16S rDNA analysis confirms these results showing that *Rhodopseudomonas palustris* and strain Rb*T* form a tight cluster together with *Bradyrhizobium japonicum* and *N. winogradskyi*, which is clearly separated from *Rhodopseudomonas acidophila* and all other members of the purple non-sulfur bacteria. The result of the DNA–DNA hybridization between strain Rb*T* and *Rhodopseudomonas palustris* differentiates them at the species level, supporting the phenotypic differences.

The chemical composition of strain Rb*T* also shows a number of features in common with members of the genera *Afipia*, *Bradyrhizobium* and *Nitrobacter*, as well as the species *Rhodopseudomonas palustris* and *Blastobacter denitrificans* (B. J. Tindall, unpublished; Moss et al., 1990; Brenner et al., 1991; Yokota & Sakane, 1991; Urakami & Komagata, 1988). Although all organisms share the presence of ubiquinone 10 as the major respiratory lipoquinone, together with 18:1ω7c dominating in the fatty acids, these are features characteristic of the majority of taxa within the α-subclass of the Proteobacteria. The presence of the four phospholipids phosphatidyl glycerol, phosphatidyl choline, phosphatidyl ethanolamine and diphosphatidyl glycerol, together with the presence of an amino hopanoid distinguishes this phyletic group of organisms (B. J. Tindall, unpublished) and further reinforces their monophyletic origin. Despite the fact that all these organisms are very similar in their chemical composition, both strain Rb*T* and *Rhodopseudomonas palustris* share the presence of an exclusively amino linked 3-OH 14:0 fatty acid. In
contrast, published data on members of the genus *Bradyrhizobium* indicate that 3-OH 12:0 and 3-OH 14:0 are present (Yokota & Sakane, 1991), whereas significant quantities of 3-OH fatty acids have not been detected in members of the genus *Afipia* (Moss et al., 1990; Brenner et al., 1991). Taken together with the ability of both organisms to grow phototrophically under anaerobic conditions, we consider these two species to constitute a distinct genus, rather than placing all members of this phyletic group in a single genus, for which the name *Nitrobacter* has priority. Considering that *Rhodopseudomonas palustris* is the type species of the genus *Rhodopseudomonas*, we propose that strain RbT be included in this genus as a new species, for which we propose the name *Rhodopseudomonas rhenobacensis* sp. nov. The question of the taxonomic position of other members of the genus *Rhodopseudomonas* is outside the scope of the present work.

**Description of Rhodopseudomonas rhenobacensis** sp. nov.

*Rhodopseudomonas rhenobacensis* (rhe.no.ba.cen′sis. M.L. adj. *rhenobacensis* pertaining to Rheinbach, a small city near Bonn, Germany, the origin of the isolate).

Cells are rods, 0.4–0.6 µm wide and 1.5–2.0 µm long. Cells multiply by budding and are motile by means of flagella. Rosette formation is found in older cultures. ICMs are of the lamellar type. Absorption maxima of the DNA is 65.5–878 nm. The optimum pH for growth is 5.0–7.0. The bacteriochlorophyll a pigments have absorption maxima of 425–430, 440–450, and 878 nm. No growth occurs under aerobic conditions. We consider these two species to be included in this genus as a new species, for which we propose the name *Rhodopseudomonas rhenobacensis* sp. nov. The question of the taxonomic position of other members of the genus *Rhodopseudomonas* is outside the scope of the present work.
