A novel *Bordetella* species was isolated from an anaerobic, dechlorinating bioreactor culture enriched from river sediment. The only strain, Se-1111R¹ (≡ DSM 12804T = CCUG 43448T), for which the name *Bordetella petrii* is proposed, is designated the type strain of the novel species. Strain Se-1111R¹ was isolated from the dechlorinating mixed culture due to its ability to anaerobically reduce selenate to elemental selenium. Comparative 16S rDNA sequence analysis showed a close relationship between Se-1111R¹ and members of the genus *Bordetella* within the β-Proteobacteria. This close phylogenetic relatedness was also reflected in several metabolic properties of Se-1111R¹, including its incapacity to utilize carbohydrates, by the high G+C content (63.8 mol%) of its DNA and by the presence of Q-8 as the major isoprenoid quinone. DNA–DNA hybridization experiments with type strains of all species of the genus *Bordetella* and closely related species *Achromobacter xylosoxidans* subsp. *denitrificans* provided further evidence for the assignment of strain Se-1111R¹ as a novel species of the genus *Bordetella*. This genus currently consists of seven aerobic species, all of which are known to occur in close pathogenic, opportunistic or possibly commensal relationships with various host organisms. *B. petrii* is the first member of this genus isolated from the environment and capable of anaerobic growth. The proposal of the novel species and an emended description of the genus *Bordetella* is presented.

**Keywords:** *Achromagenaceae*, *Bordetella*, DNA–DNA relatedness, anaerobic selenate reduction, TCB-dechlorinating bioreactor

---

**INTRODUCTION**

The family *Achromagenaceae* within the β-Proteobacteria (Woese et al., 1984, 1985) comprises the genera *Bordetella* and *Acaligenes*. Based on phenotypic and genotypic data, this family also includes the genus *Achromobacter* (Yabuuchi et al., 1998). However, until now it has not been formally assigned to the family *Achromagenaceae* and consequently the term *Acaligenes–Achromobacter–Bordetella* complex will be used throughout the text. *Bordetella* species occur exclusively in close association with humans and various warm-blooded animals, whereas *Achromobacter* and *Acaligenes* species are either environmental or facultative pathogenic organisms (Pittman, 1984; De Ley et al., 1986; Mandell et al., 1987; Busse & Auling, 1992; Yabuuchi et al., 1998).

Currently, the genus *Bordetella* comprises seven species. *Bordetella pertussis* and *Bordetella parapertussis* are aetiological agents of whooping cough (Hewlett, 1995; Matthews & Preston, 1997). Whereas *B. pertussis* is an obligate pathogen for humans, *B. parapertussis* strains are also found in sheep where they can cause chronic pneumonia. Human *B. parapertussis* isolates are highly clonal and appear to be distinct...
from the sheep isolates (Yuk et al., 1998). *Bordetella bronchiseptica* causes respiratory disease in various mammalian species including dogs, rodents, horses and pigs but only rarely in humans (Woolfrey & Moody, 1991; Gueirard et al., 1994). Recent data obtained by different molecular genetic techniques, including DNA sequence analysis of virulence genes, comparative 16S rDNA analysis, multilocus enzyme electrophoresis and IS typing, demonstrated that *B. pertussis*, *B. parapertussis* and *B. bronchiseptica* were very closely related (Mussler et al., 1986; Arico et al., 1987; Müller & Hildebrandt, 1993; van der Zee et al., 1996, 1997). These data were in agreement with previous DNA–DNA hybridization studies and showed that this group should rather be considered to be subspecies or strains of a single species with different host adaptations than presenting different species (Kloos et al., 1981; Weyant et al., 1995).

*Bordetella avium* is a pathogen for birds causing severe problems in poultry, especially in turkeys, causing coryza or rhinotracheitis (Arp & Cheville, 1984; Gentry-Weeks et al., 1992; Temple et al., 1998). Similar to the species belonging to the *B. bronchiseptica* complex, *B. avium* exhibits a strong tropism for the ciliated epithelium of the upper respiratory tract (Arp & Cheville, 1984). Physiological and genetic evidence strongly supports the classification of *B. avium* as a distinct species (De Ley et al., 1986; Weiss, 1992; Matthews & Preston, 1997). Recently, three new species were included in the genus *Bordetella*, *Bordetella hinzii*, *Bordetella holmesii* and *Bordetella trematum* (Vandamme et al., 1995, 1996; Weyant et al., 1995). *B. hinzii* is mainly found as a commensal of the respiratory tracts of fowl. It has also some pathogenic potential in immunocompromised humans (Cookson et al., 1994; Vandamme et al., 1995; Funke et al., 1996). Only recently, *B. hinzii* was reported as the causative agent of fatal septicaemia (Kattar et al., 2000). *B. holmesii* isolates, previously classified into the so-called CDC non-oxidizer group 2 (NO-2), were included into the genus *Bordetella* on the basis of genetic and chemotaxonomic analyses (Weyant et al., 1995). It has been isolated repeatedly from blood of young adults and occasionally from sputum (Weyant et al., 1995; Tang et al., 1998). The most recently described member of the genus is *B. trematum*, which was isolated from ear infections and wounds of humans, but never from the respiratory tract. Little is known about the biology of this organism and its pathogenic significance (Vandamme et al., 1996).

Most members of the genus *Achromobacter* and *Achromobaacter* are found in the environment. Some of them, *Achromobacter faecalis* and *Achromobacter xylosoxidans*, are facultative pathogens. In contrast, the *bordetellae* are generally considered to occur exclusively in close association with various host organisms. Accordingly, the obligate human pathogen *B. pertussis* is extremely fastidious and sensitive to environmental conditions. Other *Bordetella* species are more resistant against detrimental growth conditions. For example, it has been shown that *B. bronchiseptica* is able to survive for a prolonged period in buffered saline or lake water without the addition of nutrients (Porter et al., 1991). However, as yet nothing is known about the occurrence of *Bordetella* species in the environment. The adaptation to a specific host organism may have caused the loss of genetic information resulting in the reduction of some metabolic properties of these species required for survival in the environment. In fact, recent genomic sequencing projects at the Sanger Centre, UK, indicate that the genome size of *B. pertussis* is significantly smaller than that of *B. bronchiseptica*. In accordance, it has been shown recently that among the factors lost by *B. pertussis* there are genes mainly involved in metabolic functions including biosynthesis of lipopolysaccharide, amino acid metabolism and degradation of aromatic compounds (Middendorf & Gross, 1999).

In this paper, a novel *Bordetella* strain, isolated from a mixed anaerobic, dechlorinating culture, which is able to reduce selenate to elemental selenium is described. Comparative 16S rDNA sequence analysis, DNA base composition, isoprenoid quinone content, DNA–DNA hybridization experiments and several metabolic properties suggest that this organism should be classified within the *Achromobacter–Achromobacter–Bordetella* complex and assigned to the genus *Bordetella* as a novel species, for which the name *Bordetella petrii* is proposed. To our knowledge, *Bordetella petrii* is the first member of this genus isolated from the environment and capable of anaerobic growth.

**METHODS**

**Reference strains.** All bacterial strains used in this study are listed in Table 1. *B. pertussis*, *B. parapertussis*, *B. bronchiseptica* and *B. avium* strains were either grown on BG agar plates (Difco) or in SS liquid medium (Stainer & Scholte, 1970; Gentry-Weeks et al., 1992).

**Material, media and culture conditions.** Samples were taken from a fluidized bed reactor (FBR) inoculated with an anaerobic, trichlorobenzene-dechlorinating consortium enriched from sediment of the River Saale near Jena, Germany (Selent, 1999). Within the FBR, the dechlorinating consortium was immobilized on polyurethane foam cubes. The microbial diversity of this dechlorinating consortium was investigated by both PCR-amplified 16S rDNA clone libraries and 16S rDNA sequence analysis of previously obtained cellular isolates (von Wintzingerode et al., 1999; von Wintzingerode, 1999). For enrichment of anaerobic, selenate-reducing bacteria, foam cubes were removed from the bioreactor using a sterile tweezer and transferred to reduced RAMM medium (Shelton & Tiedje, 1984). After 7 d incubation at 30 °C under anaerobic conditions (GasPak anaerobic jars; Anaerogen), enrichment cultures were set up by transferring one foam cube to each Erlemeyer flask containing 50 ml Se-medium (Maucy et al., 1989) which contained (1 l−1): 2·2 g NaCl, 0·3 g KCl, 0·3 g NH₄Cl, 0·2 g KH₂PO₄, 0·15 g CaCl₂, 2H₂O, 0·4 g MgCl₂, 6H₂O, 0·6 g NaHCO₃, 3·78 g Na₂SeO₃, 3·78 g potassium acetate, 10 ml trace metal solution SL8, 10 ml vitamin solution and 800 μl methanol. After 5 d anaerobic incubation in anaerobic jars (Mant, CO₂, N₂, H₂ atmosphere), a red precipitate was

visible, which served as an inoculum for subcultures in modified Se-medium (Se-medium with 1.2 g NaCl l\(^{-1}\) and additional 1–4 g yeast extract l\(^{-1}\), 0.3 g Na\(_2\)SO\(_4\) l\(^{-1}\) and 2.02 g KNO\(_3\) l\(^{-1}\)). A pure culture was achieved by repeated streaking on agar plates containing the above-mentioned medium (1.5% agar; anaerobic incubation). Cells were stored at —70 °C in liquid growth medium supplemented with 30—50% (v/v) glycerol.

Determination of anaerobic selenate reduction. Strain Se-1111R\(^T\) was grown anaerobically in cultures containing 10 ml basic medium (Se-medium without methanol, supplemented with 0.02 g KNO\(_3\) l\(^{-1}\) and 4 g yeast extract l\(^{-1}\)) at 30 °C for 30 d. An anaerobic culture grown in basic medium without selenate served as control. An aliquot of the culture (2.5 ml) was withdrawn for determination of whole-cell elemental selenium, an aliquot of the remaining culture was treated with oxidase test strips (Merck) and by mixing cells of a single colony with a 3% (v/v) H\(_2\)O\(_2\) solution on a microscopic slide, respectively.

The API 20E, API 50CH, API 20A and API 20E were used as recommended by the manufacturer (bioMérieux). All tests were repeated at least twice.

16S rRNA sequencing and phylogenetic analyses. The nearly complete 16S rRNA genes (1523 bp) of the novel strain Se-1111R\(^T\) and reference strains B. trematum DSM 11334\(^T\), B. bronchiseptica DSM 10303, B. parapertussis DSM 4922 and Achromobacter xylosoxidans subsp. denitrificans DSM 30026\(^T\) were determined. Small subunit rRNA genes were PCR-amplified from cell lysates using primers TPU1 [5′-AGAGTTTGATCMTGGCTCAG-3′] and TPU2 [5′-AAGGAGGTGATCCAN-3′]; Escherichia coli positions 8–27] and RTU8 (5′-AAGGAGGTGATCCAN-3′; E. coli positions 1522–1541) (modified from Weisburg et al., 1991) and were subsequently cloned into the pCR2.1 vector by TOPO TA cloning (Invitrogen). 16S rDNA inserts were sequenced using IR dye-labelled vector-specific M13 primers and 16S rDNA-specific primers and the ThermoSequenase Fluorescent Labelled Primer Cycle Sequencing kit (Amersham-Pharmacia). Sequencing reactions were analysed on an automated LICOR DNA-4000L sequencer (MWG-BIOTECH). Sequence alignment and phylogenetic analyses were performed by using the ARB software package (Ludwig & Strunk, 1997). A total of 1313 bases was used for phylogenetic analyses by using the shortest 16S rDNA sequence of the alignment as a filter (Achromobacter ruhaniadii, EMBL accession no. AB010841). Uncertain sequence positions were excluded from phylogenetic analyses. Evolutionary trees were constructed by applying distance matrix (ARB, neighbour-joining with the correction of Jukes & Cantor, 1969), parsimony (ARB, PHYLIP, DNAPARS; Felsenstein, 1993) and compatibility criteria methods (ARB, PHYLIP, DNACOMP; Felsenstein, 1993). To provide confidence estimates for tree topologies, 100 bootstrap replicated resamplings were performed.

DNA base composition, DNA–DNA hybridizations and isoprenoid quinone analysis. DNA was isolated as described by Cashion et al. (1977). The mean G + C value of the DNA was determined by HPLC (Mesbah et al., 1989). The degrees of DNA–DNA binding were determined spectrophotometrically by the initial renaturation rate method (De Ley et al., 1970) with modifications described by Huß et al. (1983) and Escara.
Southern blotting. Chromosomal DNA was prepared as described by Stibitz & Garlett (1992). The bacteria were grown in the appropriate medium at 37 °C to the exponential growth phase, harvested by centrifugation and resuspended in 10 mM Tris/HCl/20 mM NaCl, pH 7.2 to give a final concentration of $2 \times 10^6$ cells ml$^{-1}$. The suspension was mixed with an equal volume of 2% (w/v) low-melting-point agarose prepared in the same buffer, pipetted into casting moulds and allowed to cool. Solidified plugs were incubated in lysozyme buffer [10 mM Tris/HCl/50 mM NaCl/0.2% sodium deoxycholate/0.5% sodium Na-laurylsarcosine/1 mg lysozyme (Merck) ml$^{-1}$, pH 7.2] with gentle agitation at 37 °C for 2 h. After washing at room temperature in 20 mM Tris/HCl/50 mM EDTA, pH 7.2, plugs were treated with proteinase K buffer [100 mM EDTA/1% sodium N-laurylsarcosine/0.2% sodium deoxycholate/2 mg proteinase K (Merck) ml$^{-1}$] at 50 °C overnight. Proteinase K was removed by washing at room temperature in 20 mM Tris/HCl/50 mM EDTA, pH 7.2 for at least 1 h. Samples were then equilibrated in TE buffer (10 mM Tris/HCl/1 mM EDTA, pH 8.0) and stored at 4 °C. For restriction enzyme digestion, slices of the plugs were incubated in 200 μl respective buffer at 50 °C for 1 h. Enzyme was then added and slices were incubated at 37 °C overnight. Reactions were stopped by addition of 20 μl 45% saccharose/100 mM EDTA containing 0.1% bromophenol blue. Plugs were then chilled on ice prior to loading onto a 1% agarose gel. Gels were run at 200 V in 0.5× TBE buffer (1× is 89 mM Tris-HCl, 89 mM borate, 0.2 mM EDTA, pH 8.0) at 14 °C in a contour-clamped homogeneous electric field DR III apparatus (Bio-Rad). Pulsed-field gels were blotted on a model 785 vacuum blotter (Bio-Rad) following the manufacturer’s instructions. For hybridization, the ECL labelling and signal detection system was used (Amersham-Pharmacia). DNA fragments containing parts of the coding regions for the pertussis toxin, adenylate cyclase toxin, dermonecrotic toxin, filamentous haemagglutinin, pertactin, fimbriae (serotypes 2 and 3), the BvgAS two-component system, the RisA response regulator and the outer-membrane protein A were used as probes for the hybridization experiments (Klein, 1999).

PCR amplification and sequencing of putative coding regions. For PCR amplification of parts of the putative open reading frames of strain Se-1111R$^T$ homologous to the ompA and risA genes of B. avium, the following primers were used which were designed according to the B. avium DNA sequences: ompA1 (5'-CCCTCAGATTGAGGCTGCCC-CTT-3'), ompA2 (5'-GTCCAGGTCCCTGCTCTACGG-TT-3'), risA1 (5'-AAAACACCATCTCCTACCAGGAAG-A-3') and risA2 (5'-CCACCTCGCCGAGGTTTGG-ATG-3'). PCR products were purified using the QIAquick PCR purification kit (Qiagen) and sequenced using an automatic DNA sequencer model ABIPRISM 377 (PE Applied Biosystems). For comparative sequence analysis, the respective programs of the GCG software package were used (Devereux et al., 1984).

RESULTS AND DISCUSSION

Cultural and morphological characteristics

Using culture conditions favouring anaerobic, respiratory selenate reduction, strain Se-1111R$^T$ was isolated from a dechlorinating microbial consortium. It formed small, irregular, slightly red coloured colonies when grown under anaerobic conditions on selenate-containing medium. Phase-contrast microscopy of 48 h LB cultures revealed non-motile, Gram-negative, predominantly short or coccoid rods (0.6 μm in width and 1.5 μm in length) with rare longer and wider forms that sometimes occurred as chains. Electron microscopy showed the presence of fimbriae on the cell surface and the occurrence of bacteriophages in the preparation (Fig. 1).

Metabolic properties

The general metabolic properties of strain Se-1111R$^T$, as well as for all other members of the genus Bordetella (Vandamme et al., 1996): aerobic and microaerobic growth at 37 °C; aerobic growth at 30 °C; assimilation of citrate; and catalase activity.

The following characteristics were negative for strain Se-1111R$^T$, as well as for all other members of the genus Bordetella (Vandamme et al., 1996): production of acetyl methylcarbinol and indole; gelatin liquefaction; ascuclin hydrolysis; and assimilation of D-

* Weyant et al. (1995).
† Weiss (1992).
‡ Positive with classical method.

Glucose, d- and L-arabinose, mannose, mannitol, N-acetylglucosamine, maltose, glycerol, erythritol, ribose, L- and D-xylene, adonitol, rhamnose, methyl β-D-xyloside, inositol, sorbitol, methyl α-D-glucoside, amygda, arbutin, salicin, cellobiose, lactose, melibiose, saccharose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, and gentiobiase. Under anaerobic conditions, no growth occurred with the following substrates: glucose; mannitol; lactose; saccharose; maltose; xylose; salicin; arabino; glycerol; cellobiose; mannose; melezitose; raffinose; sorbitol; rhamnose; or trehalose. All of the remaining characteristics are shown in Table 2.

**Anaerobic selenate reduction**

As judged from the amount of whole-cell protein, strain Se-1111R\(^T\) grew equally well under anaerobic conditions in medium containing nitrate and selenate and in medium containing only nitrate (333 µg protein ml\(^{-1}\)). The ratio of elemental selenium formed to whole-cell protein was 200 fg selenium (µg protein\(^{-1}\)).

**Phylogenetic classification**

The nearly complete 16S rRNA gene (1523 bp) of strain Se-1111R\(^T\) was sequenced. Furthermore, the 16S rRNA gene sequence of the type strain of *B. trema* (DSM 11334\(^T\)) was determined to include all *Bordetella* species in phylogenetic analyses. Fig. 2 shows the phylogenetic relationship of strain Se-1111R\(^T\) within the *Alcaligenes–Achromobacter–Bordetella* complex, as determined by comparative 16S rRNA gene sequence analyses. With all treeing algorithms, strain Se-1111R\(^T\) constituted a separate branch and *Bordetella* spp. were its closest neighbours. Strain Se-1111R\(^T\) and *Bordetella* spp. were clearly separated from a cluster comprising all validly described *Achromobacter* spp., as well as several strains isolated from a soil microarthropod (strains R5, R6 and 151; Hoffmann et al., 1998), the rhizosphere of rapeseed (strain 3-17; Bertrand et al., 1996) and trichloroethylene-degrading soil isolate KP22 (Hanada et al., 1998). Within the *Bordetella* cluster and the *Achromobacter* cluster, branching orders differed among the various algorithms. Despite variations in cluster-specific branching patterns and low bootstrap values, overall tree topologies were in agreement with recent studies, which showed that *Bordetella* spp. and members of the genus *Achromobacter* formed two closely related 16S rRNA clusters, clearly separated from *Alcaligenes* spp. (Yabuuchi et al., 1998; Kattar et al., 2000). It is therefore concluded that strain Se-1111R\(^T\) is phylogenetically affiliated to the genus *Bordetella*. Sequence similarities between strain Se-1111R\(^T\) and members of the genus *Bordetella* were 97–98% with the highest value to *B. bronchiseptica* and *B. parapertussis*. In contrast, sequence similarities to members of the genus *Achromobacter*
Fig. 2. Phylogenetic tree based on 1313 consecutive positions of the 16S rRNA gene of strain Se-1111R<sup>T</sup> and members of the genera *Bordetella*, *Achromobacter* and *Alcaligenes* within the family *β-Proteobacteria*. The dendrogram was generated using the neighbour-joining method with 100 bootstrap resamplings. Phylogenetic trees generated by the parsimony and the compatibility criterion methods showed identical overall tree topologies. Branching patterns within the *Bordetella* and the *Achromobacter* clusters changed among different algorithms. Numbers at branching points indicate bootstrap proportions of confidence in percentages (N, neighbour-joining; P, parsimony; C, compatibility). Only values &gt; 70% are shown. Zoogloea ramigera ATCC 19544<sup>T</sup> (EMBL accession no. D14254) was used as an outgroup. Bar, 10% estimated sequence divergence.

DNA base composition and isoprenoid quinone analysis

The DNA G+C content of strain Se-1111R<sup>T</sup> was 63.8±0.5 mol%. The only isoprenoid quinone detectable was Q-8.

DNA–DNA hybridizations

DNA–DNA hybridization rates determined with the type strains of all *Bordetella* spp. and *Achromobacter xylosoxidans* subsp. *xylosoxidans* were all below the threshold value of 70% (Wayne et al., 1987) indicating that strain Se-1111R<sup>T</sup> represents a distinct species (Table 1).

Identification of open reading frames highly similar to genes encoded by various *Bordetella* spp.

To investigate the presence of well-characterized genes of various *Bordetella* species, hybridization experiments were performed with DNA fragments containing parts of the genes encoding pertussis toxin, filamentous haemagglutinin, fimbriae (serotypes 2 and 3), pertactin, dermonecrotic toxin, adenylate cyclase toxin, the BvgAS two-component system, the RisA response regulator and the OmpA outer-membrane protein. Positive results were obtained for all corresponding control organisms (e.g. *B. pertussis* and *pertussis toxin* gene probe). However, with strain Se-1111R<sup>T</sup> strong and reproducible hybridization signals could be detected only for the *ompA* and *risA* genes (Fig. 3). To evaluate the degree of similarity of these DNA fragments to their *Bordetella* counterparts, parts of the coding regions of the putative *ompA* and *risA* genes were PCR-amplified using primers derived from the respective DNA sequences of *B. avium*. In both cases, PCR fragments of the expected length (461 and 445 bp, respectively) were obtained. While the *risA* genes of *B. pertussis*, *B. parapertussis*, *B. bronchiseptica* and *B. avium* are identical (Jungnitz et al., 1998), the *risA*-like gene of strain Se-1111R<sup>T</sup> contained several point mutations corresponding to a sequence divergence of 10.5%. However, all mutations found were conservative, encoding identical amino acid sequences. In the case of the *ompA* gene, strain Se-1111R<sup>T</sup> exhibited 14.0% divergence to a consensus sequence derived from the aligned DNA sequences of Se-1111R<sup>T</sup>, *B. avium*, *B. bronchiseptica* and *B. pertussis*. In contrast, *B. avium*, *B. bronchiseptica* and *B. pertussis* showed 9.1, 7.1 and 6.3% divergence, respectively.
Taxonomic position of strain Se-1111R\textsuperscript{T}

Both biochemical and chemotaxonomic characteristics showed that strain Se-1111R\textsuperscript{T} is a member of the Alcaligenes–Achromobacter–Bordetella complex. Comparative 16S rRNA gene sequence analyses affiliated strain Se-1111R\textsuperscript{T} with Bordetella spp. and clearly separated it from closely related Achromobacter spp. Despite phenotypic differences between strain Se-1111R\textsuperscript{T} and Bordetella spp. (anaerobic growth, aerobic utilization of d-glucanate), it is concluded that strain Se-1111R\textsuperscript{T} does not represent a novel genus but is a member of the genus Bordetella. DNA–DNA hybridization values obtained with the type strains of all Bordetella spp. revealed that strain Se-1111R\textsuperscript{T} represents a novel species within this genus, proposed as B. petrii.

To our knowledge, B. petrii is the first species of this genus isolated from the environment and capable of anaerobic growth. As judged from Southern blot hybridization, B. petrii does not appear to have the BvgAS signal transduction system, which regulates the infectious cycle of Bordetella species, or any of the virulence-related genes tested for. However, as all other Bordetella species and many Alcaligenes and Achromobacter species are pathogenic or facultative pathogenic organisms, the pathogenic potential of B. petrii in several infection models is in the process of being analysed.

Description of Bordetella petrii sp. nov.

Bordetella petrii [pe’trii. N.L. gen. n. petrii of Petri, named in honour of R. J. Petri, an early German microbiologist who developed the Petri-dish (Petri, 1887)].

B. petrii was isolated from an anaerobic, dechlorinating mixed culture which had been enriched from river sediment (Saale near Jena, Germany). Its pathogenic significance remains unknown. Cells are Gram-negative, non-spore-forming, non-motile and rod-shaped to circular. Cells are 0.4–0.7 µm wide to 1.0–2.8 µm in length. Cells possess fimbrae of different diameters. Colonies are of white- creamy colour and differ in size. Growth occurs under both aerobic and anaerobic conditions. Anaerobic growth is non-fermentative, possibly due to denitrification or to selenate reduction to elemental selenium. Some biochemical characteristics are described in the text and in Table 2. The major respiratory isoprenoid quinone is Q-8. The G+C content is 63.8 mol%. Strain Se-1111R\textsuperscript{T} is designated the type strain (= DSM 12804\textsuperscript{T} = CCUG 43448\textsuperscript{T}).

Emendation of description of the genus Bordetella (Skerman et al. 1980)

Based on the study of phenotypic and chemotaxonomic characteristics and comparative 16S rRNA gene sequence analysis of strain Se-1111R\textsuperscript{T}, the type strain of the species Bordetella petrii, the following emended description of the genus Bordetella is proposed.

Gram-negative, catalase-positive, asaccharolytic cocobacilli with an DNA G+C content of 60–69 mol%. Growth occurs strictly aerobically, facultatively anaerobically and non-fermentatively. One species is able to grow anaerobically under conditions favouring respiratory nitrate and selenate reduction. Species assimilate citrate under aerobic conditions, one species assimilates d-glucanate. Additional biochemical attributes are given in Results. The major respiratory isoprenoid quinone is Q-8. Strains were isolated from humans and warm-blooded animals, one strain was isolated from the environment. Based on comparative 16S rRNA gene sequence analysis, the species forms a distinct cluster separated from members of the genera Achromobacter and Alcaligenes within the β-Proteobacteria. The type species of the genus is Bordetella pertussis.

ACKNOWLEDGEMENTS

The authors would like to thank Rudi Lurz (MPI für Molekulare Genetik, Berlin) for EM-micrographs, Burkhard Selent (TU-Berlin) for running the bioreactor, Klaus Heuner and Cord Schlötelburg for helpful comments,
and Ursula Stegert and Ursula Dziuba for technical assistance. The work was supported by grants from the Deutsche Forschungsgemeinschaft (SF6749/A2 to R. G. and Sfb193/D6-YE1 and SCHN 317/6-5 to U. B. G.), by the Fonds der Chemischen Industrie (R. G.) and by the Studienstiftung des Deutschen Volkes (F. v. W.).
