Three Gram-positive, anaerobic, non-spor-forming, rod-shaped bacteria with pointed ends were isolated from clinical specimens. The organisms were weakly saccharolytic and produced indole, acetate, butyrate and lactate as major metabolic end products. 16S rRNA gene sequence analysis indicated that the isolates had no known close relatives among recognized bacteria but that they exhibited a phylogenetic association with Clostridium rRNA cluster XIVa [as defined by Collins, M. D. et al. (1994). Int J Syst Bacteriol 44, 812–826]. The closest recognized relatives were the type strains of Clostridium clostridiiforme, Clostridium bolteae and Clostridium asparagiforme (16S rRNA gene sequence similarity values of 90.2–91.4 %). These results suggest that these three clinical isolates represent a novel species of a new genus, for which the name Moryella indoligenes gen. nov., sp. nov. is proposed. The type strain of Moryella indoligenes is AIP 220.04T (=CIP 109174T = CCUG 52648T).

Anaerobic bacteria constitute an important part of the human microbial community. Although the majority are considered to be commensals, many of them behave as opportunistic pathogens. Notwithstanding intensive investigations by using conventional identification techniques, we still know relatively little about the bacterial diversity of these microbial communities. Indeed, molecular genetic tools have indicated that 60–80 % of organisms in the total human microflora have not been cultivated (Langendijk et al., 1995; Suau et al., 1999) and only 24 % of the molecular species recovered from the human intestinal tract corresponded to recognized species (Suau et al., 1999). Thus, the combination of genetic tools and traditional phenotypic methods of identification should be used whenever possible with the aim of providing greater knowledge of these ‘hidden’ bacteria. Here we report on the characterization of an indole-producing anaerobic bacterium that was recovered from different clinical specimens. Phylogenetically, the strains described represent a hitherto unknown subsline within the Clostridium cocoides rRNA group. Based on the data presented, we describe a novel species in a new genus for these strains.

The new isolates were recovered from clinical sources: strain AIP 241.03 from a buttock abscess, strain AIP 220.04T from an intra-abdominal abscess (both from France) and strain MDA2477 from a polymicrobial thigh abscess (from Houston, TX, USA). Thus, these strains might all have originated from the intestinal tract. The strains were maintained in trypticase/glucose/yeast extract medium (TYG) consisting of 95 % H2 and 5 % CO2 (v/v). Colony morphology determinations and presumptive identification tests (Engelkirk et al., 1992) were performed on Wilkins–Chalgren agar plates. Biochemical reactions were examined according to the procedures described by Holdeman et al. (1977). Metabolic end products were assayed by quantitative GC as described by Carlier (1985). For electron microscopy, cells were prepared as described by Carlier et al. (2004), and electron microphotographs were taken with a JEOL 1010 transmission electron microscope operating at 80 kV.

Colonies appeared on Wilkins–Chalgren blood agar after 24–48 h incubation. They were circular, convex, about 0.5–1 mm in diameter, non-pigmented and non-haemolytic. Cells were elongated, sometimes warped rods with pointed ends, about 0.8–1.7 μm long and 0.5–0.6 μm wide, usually occurring singly, in pairs or occasionally in short chains (Fig. 1a). They were non-motile, Gram-variable after staining but structurally Gram-positive (Fig. 1b). Spore formation was not observed.
The isolates were strictly anaerobic. They were susceptible to discs containing 1 mg kanamycin, 10 μg colistin, 5 μg vancomycin and 4 μg metronidazole and to bile discs. They were indole-positive. Catalase activity and nitrate and nitrite reduction were not detected. Gelatin was not liquefied and milk was not modified. Glucose, galactose, maltose and ribose fermentation were variable. Acid was not produced from raffinose, sucrose, aesculin, arabinose, cellobiose, fructose, glycerol, inositol, lactose, mannitol, mannose, fructose, glycerol, inositol, lactose, mannitol, mannose, melezitose, melibiose, rhamnose, salicin, sorbitol, starch, trehalose or xylose. Aesculin was not hydrolysed. The major metabolic end products were acetic acid (6.4–14 mmol l⁻¹), butyric acid (12–28 mmol l⁻¹) and lactic acid (6–25 mmol l⁻¹). Table 1 provides the primary characteristics of these isolates that can be used to differentiate them from several closely related species.

The G+C composition of strain AIP 220.04ᵀ was 50.2 mol%, as determined by HPLC at the Identification Service of the DSMZ (German Collection of Microorganisms and Cell Cultures). Cellular fatty acid composition was analysed by GC according to Veys et al. (1989). Briefly, the three strains were grown anaerobically in 10 ml TGY for 48 h and chromatography of the methyl esters was on a fused-silica capillary column (25 m × 0.25 mm ID) coated with 5% methyl phenyl silicone. Fatty acid methyl ester analysis showed that the strains contained an unknown compound that eluted between C₁₂:₀ and C₁₃:₀ (14%), C₁₄:₀ (47%) and C₁₆:₀ (9%) as the major components. Minor fatty acids included C₁₂:₀ (3.4%), iso-C₁₄:₀ (2.7%), iso-C₁₅:₀ (2.4%), anteiso-C₁₅:₀ (7%), a second unknown compound that eluted between C₁₄:₀ and iso-C₁₅:₀ (6.2%), iso-C₁₆:₀ (1.4%), C₁₆:₁₀9c (2.6%) and C₁₈:₀ (1.4%). No hydroxy fatty acids were detected.

The 16S rRNA gene sequences were determined for each strain as described by Carlier et al. (2004). Alignment was via the CLUSTAL W program (Thompson et al., 1994). Regions showing alignment uncertainties and gaps were excluded and 1375 unambiguous nucleotide positions were used. A distance matrix was calculated by using DNADIST with the Jukes–Cantor parameter (Jukes & Cantor, 1969). A phylogenetic tree (Fig. 2) was constructed according to the neighbour-joining method with 100 bootstrap resamplings (Felsenstein, 1993). Sequence comparison revealed that the new isolates shared more than 99.9% 16S rRNA gene sequence similarity with each other and had no known close relatives among recognized bacteria. Indeed, the nearest phylogenetic neighbours were the type strains of Clostridium clostridioforme, Clostridium bolteae and Clostridium asparagiforme, with sequence similarity values of 90.2–91.4%.

The new isolates formed a distinct lineage within the C. cocoides rRNA group of organisms, and the monophyly of this lineage was strongly supported by the high bootstrap value of 98%. Thus, these isolates were considered to represent a novel taxon. Within the lineage, an oral clone MCE9_173 branched off; this clone, described by Munson et al. (2002) as ‘Lachnospiraceae’, shared 93.4% sequence similarity with the novel organism. To determine the genus and species status of the novel organism, its relationship with members of the C. cocoides rRNA cluster was examined. This cluster encompasses a phenotypically heterogeneous collection of organisms, including sporforming and non-spor-forming genera and species. Several butyrate-producing members are also widely distributed within this cluster (Barcenilla et al., 2000). Although the novel bacterium was phylogenetically closer to the C. clostridioforme group, it differed from these clostridia because it was not a spore-former and produced butyrate. On the other hand, it was phylogenetically too distant from the butyrate-producing members to be assigned to those genera or species. Thus, given the ~10% 16S rRNA gene sequence divergence from their closest relatives and several distinct phenotypic features, the three strains are considered to represent a novel species of a new genus, for which the name Moryella indoligenes gen. nov., sp. nov. is proposed.

**Description of Moryella gen. nov.**

*Moryella* (Mo.ry.el’la. L. fem. dim. ending -ella; N.L. fem. n. *Moryella* named in honour of the French microbiologist Francine Mory, who has contributed to our understanding of anaerobes).

Cells are Gram-variable after staining but structurally Gram-positive, elongated, non-motile rods with pointed ends. Cells may lose their colour easily. No spores are formed. Strictly anaerobic, without growth under...
Table 1. Characteristics that differentiate the three new clinical strains from other close relatives

ND, Not determined/no data available; V, strain variation; d, 11–89 % of strains positive.

Microaerophilic or aerobic conditions. Catalase and urease reactions are negative. Nitrate is not reduced. Indole-positive and weakly saccharolytic. The major metabolic end reactions are negative. Nitrate is not reduced. Indole-production is the main biochemical characteristic of the species. Glucose, galactose, maltose and ribose fermentation are variable. Acid is not produced from any of the following carbohydrates: raffinose, sucrose, aesculin, arabinose, cellobiose, fructose, glycerol, inositol, lactose, mannitol, mannose, melezitose, melibiose, rhamnose, salicin, sorbitol, starch, trehalose or xylose. Aesculin is not hydrolysed. Gelatin is not liquefied and milk is not modified. The type strain is susceptible to ampicillin, amoxicillin, penicillin G, imipenem, cefalotin, cefotaxim, cefoxitin, latamoxef and metronidazole, moderately resistant to tetracycline and resistant to trimethoprim–sulfamethoxazole, erythromycin and rifampicin. Strains AIP 241.03 and MD2477 are resistant only to trimethoprim–sulfamethoxazole and erythromycin. The DNA G+C content is 50.2 mol%. Habitat is not known, but likely to be the human gut.

The type strain, AIP 220.04T (=CIP 109174T =CCUG 52648T), was isolated from a clinical specimen from an intra-abdominal abscess. Strains MD2477 (=ATCC BAA-695) and AIP 241.03 are additional strains of this species.

Description of Moryella indoligenes sp. nov.
Moryella indoligenes (in.do.li.ge.nes. N.L. n. indolium indole; N.L. suff. -genes producing from Gr. v. geneía to produce; N.L. part. adj. indolgenes indole-producing).

Displays the following properties in addition to those given in the genus description. Cells are sometimes warped, about 0.8–1.7 μm long and 0.5–0.6 μm wide, occurring singly, in pairs or occasionally in short chains. Colonies are circular, convex and about 0.5–1 mm in diameter on Wilkins-Chalgren blood agar after 24–48 h incubation, non-pigmented and non-haemolytic. Catalase and urease activities are positive. The genus belongs to the Clostridium biforme sp. nov. (rRNA cluster XIVa; Collins et al., 1994). The type species is Moryella indoligenes.
