Gardnerella vaginalis has a gram-positive cell-wall ultrastructure and lacks classical cell-wall lipopolysaccharide

K. SADHU, P. A. G. DOMINGUE*, A. W. CHOW†, J. NELLIGAN, N. CHENG† and J. W. COSTERTON

Summary. Gardnerella vaginalis has a very thin cell wall with a characteristic gram-negative staining pattern and an apparent lamellar structure when viewed at an oblique angle by electronmicroscopy. Examination at right angles to the cell-wall plane and by freeze-etching showed absence of an outer membrane or any other lamellar structure. Cell-wall extracts made by methods specific for lipopolysaccharide (LPS) gave negative reactions by silver staining and for endotoxin in the limulus amoebocyte lysate assay. 2-Keto-3-deoxy-β-manno-2-octonoic acid (KDO), heptose and hydroxy fatty acids specific for LPS were not detected in the extracts. G. vaginalis cell walls are unequivocally gram-positive in their ultrastructural characteristics and chemical composition.

Introduction

Gram's stain generally distinguishes two different types of bacterial cell wall, conveniently called gram-positive and gram-negative. These differ radically in chemical composition and molecular architecture (Costerton et al., 1974; Beveridge, 1988) and these structural differences form the basis of significant differences in their sensitivity to antibiotics and in enzyme release patterns (Beveridge, 1988). Gram-negative bacteria are characterised by an elaborate outer membrane that lies outside the cytoplasmic membrane and regulates the passage of solutes into the periplasmic space (Costerton et al., 1974). Paradoxically, Gram's stain clearly identifies gram-positive bacteria that have thick and intact matrix-like cell walls, but it identifies as gram-negative not only those with the typical, double membrane, gram-negative cell-wall structure but also bacteria that have thin, aged, or damaged cell walls (Beveridge, 1988). An example is Butyrivibrio fibrisolvens which has a wall of classic gram-positive chemistry and molecular architecture, completely lacking the gram-negative outer membrane, but which is gram-negative because the cell wall is too thin (c. 15 nm) to retain the violet stain (Cheng and Costerton, 1977).

The nature of the cell wall of Gardnerella vaginalis has long been a subject of dispute. It does not retain crystal violet during conventional gram-staining procedures, but displays gram-positive features such as definite septum formation during cell division (Reyn et al., 1966). The antibiotic sensitivity pattern of G. vaginalis also resembles that of gram-positive bacteria (Piot et al., 1980). Transmission electronmicroscopy (TEM) of sectioned material has shown that the cell walls of G. vaginalis are thin and somewhat lamellar, and this structure has been variously interpreted as "typically gram-positive" (Reyn et al., 1966), "trilaminar" (Criswell et al., 1972), and "more closely resembling that of a gram-negative (organism)" (Greenwood and Pickett, 1980).

Analysis of the cell-wall composition of G. vaginalis reveals that only 20% of the total cell-wall weight is peptidoglycan (Criswell et al., 1971) which is rather low for a gram-positive organism. Criswell et al. (1971) also found many amino acids, including lysine but not diaminopimelate (DAP), present in the peptidoglycan; therefore, they described the organism as a gram-negative bacterium. Their results have been refuted by Piot et al. (1980), Harper and Davis (1982) and O'Donnell et al. (1984) who, in contrast, found simple amino-acid profiles that included lysine. DAP, common to
many gram-negative cell walls, and found in a few
gram-positive species (Harper and Davis, 1982),
was not found. Subsequently, the diamino acid in
the G. vaginalis wall was confirmed as lysine
(O'Donnell et al., 1984), thus explaining the absence
of DAP. The studies of Criswell et al. (1971, 1972)
have been further faulted because the amino-acid
profiles for their control organisms were at variance
with currently accepted work (O'Donnell et al.,
1984; Harper and Davis, 1982).

Ribitol teichoic acid was reportedly absent from
the cell walls of G. vaginalis (Criswell et al., 1971)
but it is not universally present in gram-positive
cell walls. Greenwood and Pickett (1980) prepared
material from the cell wall of G. vaginalis by hot
aqueous phenol extraction; they regarded it as a
“lipopolysaccharide (LPS)-like” substance. This
did not contain 2-keto-3-deoxy-d-manno-2-octo-
oinic acid (KDO) (Greenwood and Pickett, 1980;
Piot et al., 1980) or hydroxy fatty acids (Greenwood
and Pickett, 1980; O'Donnell et al., 1984) and gave
positive results for endotoxin in the limulus amoeb-
cocyte lysate (LAL) assay only at very high
concentrations (Greenwood and Pickett, 1980).
Heptose sugar and dideoxy sugar are also absent
from the cell walls of G. vaginalis (Harper and
Davis, 1982). Therefore, it is doubtful whether G.
vaginalis contains LPS, at least of the classical
variety. The “LPS-like” substance of Greenwood
and Pickett (1980) could be a lipoteichoic acid
because they share certain characters with lipopo-
lysaccharides (Wicken and Knox, 1975). We pre-
sent here the results of further ultrastructural and
chemical studies of the G. vaginalis cell wall.

Materials and methods

Bacterial strains and growth conditions

G. vaginalis ATCC 14018 and clinical isolates 7642,
7803 and 7644 were examined. They were grown in Brain
Heart Infusion Broth (Difco Laboratories, Detroit, MI,
USA) supplemented with Proteose Peptone Number 3
(Difco) 5% w/v and soluble starch (Difco) 5% w/v, to
mid-exponential phase with shaking at 37°C in a CO2
incubator (Hotpack, Waterloo, Ontario).

Transmission electronmicroscopy, TEM

Bacteria were pre-fixed by the addition of nine parts
of glutaraldehyde 5% v/v to one part of broth culture, for
2 h at 22°C. After spontaneous settling of bacteria, the
broth + pre-fixative was decanted and the cells were fixed
in ruthenium red 0·15% w/v and glutaraldehyde 5% v/v
in 100 mM cacodylate buffer, pH 7·2, for 2 h at 22°C. All
subsequent washing used this buffer but with the inclusion
of ruthenium red 0·05% w/v. After two washes, the
bacteria were agar-enrobed and washed five times. They
were then post-fixed in buffer containing OsO4 2% v/v
for 2 h at 22°C. After five washes, the agar cores were
dehydrated in aceton series (30%, 50%, 70%, 90%
and 100% v/v). The first three dilutions were in buffer
but the 90% dilution was in double distilled water due to
limitations in ruthenium red solubility. Each stage lasted
20 min except the 90% and 100% washes which lasted
5 min to minimise loss of stain. Cores were further
dehydrated for two 10-min periods in propylene oxide
before they were embedded in low viscosity resin (Spurr,
1969). Sections were cut to c. 60 nm and stained with
uranyl acetate and lead citrate (Reynolds, 1963) before
carbon stabilisation. They were examined at an acceler-
ation voltage of 50 kV (Model H-600; Hitachi, Tokyo,
Japan).

Freeze-etching and scanning electronmicroscopy,
SEM

Cultures were pelleted by centrifugation at 3000 rpm,
for 10 min, at 4°C and drops of deposit were affixed to
ridged copper disks (3 mm diam; Balzers; Technical
Marketing, Vancouver, Canada) in the absence of
cryoprotective agents and immersed in liquid Freon 22
maintained around its melting point. Freeze-etching
(BA 360 M; Balzers) was performed with cleavage at
−100°C and was followed by etching of the surface by
sublimation for 5 s. The platinum coating was applied
from an angle of approximately 45° and specimens were
then examined by SEM (Model S450; Hitachi).

LPS extraction

Lyophilised cells were extracted with hot aqueous
phenol (Westphal and Jann, 1965) and by an EDTA-
enzymatic method (Darveau and Hancock, 1983). Ab-
sorbance scans (A300–A200) were performed on final
extracts to monitor protein and nucleic acid contamina-
tion.

Chemical analysis of LPS

Lyophilised LPS prepared by both of the above
methods was submitted to a limited range of chemical
analyses. Sodium dodecyl sulphate-polyacrylamide gel
electrophoresis (SDS-PAGE; Laemmli, 1970) with 12%
gels was used to prepare LPS for subsequent silver
periodate staining (Tsai and Frasch, 1982). Assays for
(KDO) were as described by Osborn et al. (1972) except
that a 15-min hydrolysis in 0·5 N sulphuric acid was
included (Darveau and Hancock, 1983). Heptose, an
LPS-specific sugar, was assayed as described by Wright
and Reber (1972) with D-glycero-L-mannoheptose
standard. The presence of 3-hydroxy C14–C18 fatty acids
was determined by GLC as described by Kropinski et al.
(1982). The reactivity of extracts in the LAL test was also
determined (Hochstein et al., 1983).
Results

Electronmicroscopy

Cells of all four strains had thin walls (8–12 nm) that were sometimes lamellar but never contained the outer membrane typical of gram-negative cell walls (fig. 1, a–d). G. vaginalis walls were fibrillar and unstructured and, where the clear resolution of the underlying cytoplasmic membrane indicated that the sectioning was at right angles to the cell surface (fig. 1, a–d, thick arrows), they were seen to be separated from this inner structure by an electron-transparent zone. In other areas in which the cell envelope was not sectioned at right angles, an illusion, based on Moiré patterns, of lamellar cell-wall structure was produced (fig. 1a and 1c, asterisk) or cell walls appeared thickened (fig. 1b and 1d, asterisk). A small proportion of cells produced thickened septa (fig. 1b, S) and fibrillar residua of dehydration-condensed extracellular polysaccharides (fig. 1a, c and d; fig. 2b, thin arrows) were seen in many of these organisms. Dividing cells of all four strains produced the well-defined septa characteristic of gram-positive cells. A small proportion of cells produced thickened septa when their peripheral cell walls were thin (fig. 1b, S) or thick (fig. 2b, S). Freeze-etching of cells of all four strains showed the absence of an outer cleavage phase and demonstrated thick septa (fig. 2a, S). The thick peripheral walls of cells (fig. 2b) were generally fibrillar and unstructured and sometimes attained a thickness (c. 50 nm) typical of the cell walls of conventional gram-positive organisms. Electron-dense strands of condensed exopolysaccharide material were seen at the surfaces of many of these cells and these condensed strands sometimes appeared to mediate cell-to-cell aggregation (fig. 1a and 1d, thin arrows).

LPS investigations

Absorbance scans indicated that at 280 nm and 260 nm, there was <0.1% of protein and <1-0% of nucleic acid; the Darveau-Hancock preparations were even cleaner (data not shown). Furthermore, proteins were not detected in silver-stained preparations of SDS-PAGE gels. Silver-staining reactions were not obtained with extracts from any of the G. vaginalis strains or the negative control ATCC 27217. In contrast, and further confirming correct experimental procedure, a smooth strain of Salmonella typhimurium gave a full LPS “ladder” pattern and a rough strain gave a smear at the bottom of the gel, characteristic of rough LPS (data not shown). For convenience, and because no significant differences were detected between LPS extracts prepared by the two methods, results averaged out for each organism are presented in the table. Only the Salmonella strains gave reactions typical of gram-negative bacteria, with the expected differences between smooth and rough variants.

Discussion

It is acknowledged that ageing affects the integrity of the cell wall both ultrastructurally and in Gram’s stain (Beveridge, 1988) and gram-positive envelope characteristics are known to reflect sampling positions during the growth cycle (Domingue et al., 1988). The results of our electron-microscopy emphasise the value of using actively growing bacteria.

The sections used for examination of the ultrastructure of bacterial cell walls have a finite thickness and, therefore, very thin structures, such as the cytoplasmic membrane (c. 8-5 nm), must be sectioned almost exactly at right angles for correct resolution. Where the cytoplasmic membrane is properly resolved (fig. 1, a–d, thick arrows), the cell wall would be expected to lie at or close to a right angle and the walls of most cells of four strains of G. vaginalis were clearly very thin (8–12 nm), homogeneous, fibrillar structures when observed in

* Units/mg of LPS extract (dry weight).
† Endotoxin units/mg of LPS extract (dry weight).
Fig. 1. Electronmicrographs of ruthenium red-stained sections of cells of *G. vaginalis*: (a) ATCC strain # 14018; (b) clinical isolate # 7642; (c) clinical isolate # 7803; and (d) clinical isolate # 7644. An electron-transparent zone (thick arrows) is apparent between the cytoplasmic membrane and the very thin wall when the envelope is sectioned at right angles to the cell surface. When sectioning is not at right angles, either a Moiré-based illusion of lamellar walls is produced (asterisk; a and c) or walls may appear thickened (asterisk; b and d). Thickened septa (S) are found in the presence of thin peripheral cell walls (b). Electron-dense, dehydration-condensed, fibrillar exopolysaccharide is present (thin arrows; a, c, d). Bars = 0.1 μm.
Fig. 2 (a) Electronmicrograph of a freeze-etch preparation of cells of *G. vaginalis* (strain 7642) showing the absence of an outer-membrane cleavage plane and the presence of a thick septum (S) of gram-positive type. (b) Electronmicrograph of a ruthenium red-stained section of cells of *G. vaginalis* (strain 7803) showing the rare presence of both thickened septa (S) and thickened peripheral cell walls. Electron-dense, dehydration-condensed fibrillar exopolysaccharide (thin arrows) are seen at the cell surface. Bars = 0.1 μm.
these areas. No outer-membrane structures were seen within these cell walls and, in addition, outer-membrane cleavage planes were not demonstrable by freeze-etching, indicating the absence of an outer membrane (Costerton et al., 1974).

Occasional cells of all four strains produced thick septa of the classic gram-positive type and, less commonly, some cells produced thick peripheral cell walls that were similarly homogeneous without signs of an outer-membrane structure. These thick structures resembled those of conventional gram-positive bacteria in thickness (c. 50 nm), in fibrillar homogeneity, and in the complete absence of an outer-membrane structure.

The thinness of the walls of most cells of this organism can account for their tendency to stain gram-negative or gram-variable (Cheng and Costerton, 1977). The lamellar appearance produced when these thin structures are seen at an oblique angle (fig. 1a–d, asterisk) may account for repeated reports of layered cell wall structures in this organism (Criswell et al., 1971, 1972; Greenwood and Pickett, 1980).

To support electronmicrographic data, gram-positive and gram-negative reference strains that included a G. vaginalis control and a clinical isolate (7803) were treated with extraction methods for LPS. These methods yielded products that gave expected reactions for all control strains in a limited range of tests. The G. vaginalis strains were similar to Staphylococcus aureus in that negative reactions were obtained in tests that gave positive results with the salmonellae. KDO values for the smooth Salmonella strain were probably underestimates because of interference in the assay by abequose present in the O antigen. However, reactions with the silver stain, and in GLC for the LPS-specific hydroxy fatty acids, confirmed our methodology and extraction procedures. Also, both G. vaginalis strains gave negative reactions in the LAL assay which, though not specific for LPS, is much more sensitive to it than to other amphiphiles such as lipoteichoic acid (LTA) (Wicken and Knox, 1980).

It may be that G. vaginalis does not contain classical LPS or LTA but rather an entity related to the membrane lipocarbohydrate antigen of Sharp and Poxton (1986).

We conclude, with Reyn et al. (1966), that at the ultrastructural level the cell walls of G. vaginalis show gram-positive organisation, but that these structures are unusually thin in most cells thereby contributing to the mistaken assumption that they are gram-negative. This conclusion is supported by our chemical analysis which is in accord with more recent reports.
