MAREK's disease (Marek, 1907) is an infectious lymphoproliferative disorder of chickens characterised by neural infiltration with lymphocytes and plasma cells, by visceral lesions and by uveitis.

The neural form is most frequent, but all forms may occur either separately or in any combination. The visceral and, occasionally, the neural forms of the original, or classical, type of disease are characterised by tumours that appear, at any rate initially, to be of an inflammatory nature and have been termed lymphogranulomas (Campbell, 1956). These may subsequently undergo malignant transformation to form lymphoblastomas. An acute form has appeared in the last decade, which from its onset shows a much higher incidence of malignant tumours involving viscera, subcutaneous tissue and nerves.

This relatively new and highly infectious disease has been the subject of intensive research in recent years, and a strongly cell-associated, herpes-type virus, possibly belonging to sub-group B, has been regularly isolated and is considered to be the likely cause (Churchill and Biggs, 1967, 1968; Epstein et al., 1968; Nazerian et al., 1968; Solomon et al., 1968). The methods employed by these workers involved the establishment of healthy monolayer cultures of chick kidney cells, or chick or duck embryo fibroblasts, and their subsequent infection with material from experimentally maintained strains of the disease or from field cases. Usually, prolonged culture and serial passage were necessary before a visible cytopathic effect was produced and virus was demonstrable by electron microscopy. Acute Marek's disease is readily transmitted by the inoculation of whole blood into young chicks, although some lines of fowls are more susceptible than others. Cell-free plasma has proved to be less effective as an inoculum than whole blood (Biggs and Payne, 1967; Witter, Burgoyne and Solomon, 1968; Glaser et al., 1969), but the formed element in the blood that carries the infective agent has not been identified. The more chronic, classical form of the disease has been equally intensively investigated since it was first described by Marek. It is a disease difficult to transmit experimentally and its aetiology, although presumptively similar to that of the acute form, remains unestablished.

The present paper reports a method that makes possible the rapid detection of intranuclear, herpes-type virus in "blast"-like, transformed lymphocytes from the blood in both the classical and acute forms of Marek's disease, by employing a short-term tissue-culture method adapted from the simple standard technique used in chromosomal analysis of blood. Cells containing naked and coated virus are readily obtained, and are very suitable for the study of viral
replication, for studies of infection in vitro and possibly also in vivo, and for immunological investigations.

**MATERIALS AND METHODS**

**Chickens**

The chickens were mostly derived from the Edinburgh Poultry Research Centre's flock of Brown Leghorns, line B, in which classical Marek's disease is endemic. Material from acute field cases and experimentally infected cases was obtained from Dr J. E. Wilson, Veterinary Laboratory, Ministry of Agriculture, Fisheries and Food, Lasswade, Midlothian, who also arranged for us to collect blood samples from a small flock of fowls reared in isolation and in which no Marek's disease had occurred in the parent stock and the first generation progeny during 15 mth.

**Collection of lymphocytes**

Lymphocytes for culture were obtained from both affected and clinically normal chickens by withdrawing 10 ml blood from the brachial vein into a heparinised syringe and transferring it to a centrifuge tube containing 0·2 ml phytohaemagglutinin. The blood was allowed to stand at room temperature for 1–2 hr and then centrifuged for 10–12 min. at 130g. Plasma with suspended cells was transferred with a pasteur pipette to another tube and centrifuged at 640g for 10–15 min. After the supernatant plasma had been removed, the cell pellet was washed twice with phosphate-buffered saline (NaCl 8·5 g, Na₂HPO₄ 1·07 g, NaH₂PO₄.2H₂O 0·39 g, and water 1 litre, pH 7·1) centrifuged, and finally resuspended in 2 ml foetal bovine serum. The cells, when examined by phase-contrast, were seen to be mostly lymphocytes with some monocytes. In later modifications of the method, which gave marginally better results, the blood was withdrawn into a syringe containing 1 ml of 3·8 per cent. sodium citrate and the phytohaemagglutinin was added to the complete culture prior to incubation.

**Culture of lymphocytes**

Growth medium consisted of Eagle’s Minimal Essential Medium (Flow Laboratories) containing penicillin 100 units per ml and streptomycin 100 µg per ml, supplemented by the addition of 0·3 ml of 5 per cent. glutamine and 0·1 ml of 10 per cent. sodium bicarbonate per 100 ml. The 2-ml volume of lymphocyte suspension in foetal bovine serum was added to 8 ml of the supplemented Minimal Essential Medium, giving a final concentration of 20 per cent. serum in the medium. Incubation was at 37°C and was done in 25-ml screw-capped glass bottles or in Falcon plastic tissue-culture bottles (Falcon Plastics, Los Angeles, California; Agents: Townsend and Mercer Ltd, Edinburgh). The bottles were either gassed individually with a mixture of 5 per cent. CO₂ in air and then tightly stoppered, or incubated with loose stoppers in the CO₂-air mixture in double-tapped Perspex boxes containing a dish of phenol-red indicator, which provided humidity and a check on atmospheric pH. Falcon bottles were incubated flat or slightly inclined, and glass bottles were incubated upright. Cultures were usually maintained for periods of about 72–90 hr, with extremes of 65–165 hr.

**Electron microscopy**

After incubation the cells were resuspended, transferred to a centrifuge tube and spun at 640g for 10 min. The medium was discarded and the cells were washed twice with phosphate-buffered saline and centrifuged. After the supernatant fluid had been decanted, about 5 ml of 5 per cent. glutaraldehyde in phosphate-buffered saline (pH 7·1) was carefully pipetted on to the packed cells. Fixation was for 1 hr, after which the pellet was washed in three successive changes of phosphate-buffered saline, post-fixed for 1 hr in 2 per cent. osmium tetroxide and processed for embedding in Araldite. Sections were cut with an LKB ultramicrotome and stained with uranyl acetate and lead citrate. They were examined with a Philips EM300 electron microscope.

Fig. 2.—Transformed lymphocyte with intranuclear virus particles, from a 72-hr culture of lymphocytes from a case of classical Marek's disease. The large size and margined chromatin allows rapid identification of infected cells at low magnification. Electron micrograph (EM). \( \times 16,190 \).
Fig. 3.—Intranuclear immature herpes-type particles in a cultured transformed lymphocyte from a case of classical Marek's disease. Note hexagonal profile and variably dense nucleoid (arrows), also an outpocketing of the irregular nuclear membrane. EM. × 79,800.
Films of cultured lymphocytes and flying coverslip preparations of infected kidney monolayers were stained with methyl green-pyronin (Kurnick, 1955) or haematoxylin and eosin for conventional microscopy, and with coriphosphine 0 by the method of Keeble and Jay (1962) for fluorescence microscopy.

Antisera for immunofluorescence. These antisera were derived either from chickens experimentally infected with acute Marek's disease and kindly donated by Dr P. M. Biggs, or from animals with naturally occurring infections of the classical form, some of which, in an effort to boost antibody, had received repeated intramuscular injections of blood from classical cases, plus Freund's complete adjuvant.

Immunofluorescence method. The indirect, or double layer, method was used for immunofluorescence studies. Monolayers and smears were washed gently in three changes of phosphate-buffered saline, dried at 37°C for 1 hr, fixed for 10 min. in acetone, and dried in an incubator. All preparations were processed immediately. The first layer of reagent applied was a 1 in 10 dilution of homologous antiserum in phosphate-buffered saline. It was allowed to act for 30 min. in a moist chamber. Control preparations were treated with normal serum or infectious laryngotracheitis antiserum (kindly given by Mr A. J. MacLeod, The Wellcome Foundation Ltd) in place of serum from Marek's disease. The preparations were washed with constant stirring for 1 hr in a large volume of phosphate-buffered saline and then stained for 30 min. with the second layer of reagent, which consisted of a 1 in 10 dilution of horse anti-chicken gamma-globulin tagged with fluorescein isothiocyanate (Progressive Laboratories Inc., Baltimore) in phosphate-buffered saline, again in a moist chamber. After being washed for at least 1 hr as before, the preparations were mounted in a 90 per cent. solution of glycerol in phosphate-buffered saline and examined for fluorescence excitation under ultraviolet radiation in a Zeiss photomicroscope with a phase-contrast fluorescence condenser, exciter filter BG/12 and barrier filter 50.

Tissue culture

Chicken kidney cells were cultured by the method of Churchill (1965) modified by the substitution of a culture medium that gave better results than either Churchill's medium or that of Kawamura, Isogai and Tsubahara (1961). The growth medium consisted of Hanks' Salt Solution (Burroughs Wellcome and Co.) with 0·5 per cent. lactalbumin hydrolysate (V. A. Howe and Co.), 10 per cent. calf serum, 0·044 per cent. sodium bicarbonate, penicillin 100 units per ml, and streptomycin 100 µg per ml. For maintenance, a similar medium containing 2 per cent. calf serum and 0·088 per cent. sodium bicarbonate was used.

Cell monolayers on glass were confluent in 3–5 days, and were maintained satisfactorily for up to 12 wk. Cultures from birds aged 3–12 wk required an inoculum of 8 × 10⁴ viable cells per ml, and those from birds aged 13–16 wk required one of 1·6–3 × 10⁶ cells per ml. The age of the bird did not appear to influence the quality of the culture produced. The calf serum was filtered through a Sartorius membrane filter with a pore size 0·2 µm. It was not heat-treated at 56°C, since such heating had been found to be deleterious for the growth of cells.

RESULTS

Lymphocyte cultures

Optimum survival with cell transformation to a "blast" form was obtained with 72–96 hr cultures, although on one occasion transformed cells were seen at 48 hr. Usually the lymphocytes tended to degenerate when incubation was prolonged to more than 144 hr, although one culture showed excellent survival at 165 hr. Prolonged culture was possible, since in one instance lymphocytes from a healthy control were maintained through 11 changes of growth medium.
during a period of 5 wk, in the course of which they underwent conversion to
a slowly growing syncytium of histiocyte-like cells.

At 24 hr, cultures almost always showed "satellitosis" of lymphocytes
around a larger macrophage-like cell. These clumps increased in size and
eventually formed conspicuous "rosettes" (fig. 1).

**Electron-microscope appearances.** About 4 per cent. of the cultured lympho-
cytes transformed into "blast" cells. These transformed cells, taken from
birds subsequently shown to have suffered from acute or classical Marek's
disease, were easily recognisable, being 2–4 times the size of unaltered lympho-
cytes (fig. 2). They had an increased cytoplasm:nucleus ratio, large, often
irregular-shaped, vesicular nuclei, margined chromatin and, occasionally,
disruption of the nuclear membrane. Typical, hexagonal herpes-type virus
particles, similar to those described by Epstein *et al.* and Nazerian *et al.*, were
present in many of the transformed cells. The majority were immature,
having a single envelope surrounding a nucleoid of variable density, and
measured 94 × 74 nm in diameter (fig. 3). Empty and double-enveloped par-
ticles were occasionally seen, although the latter only rarely. They measured
120 nm in diameter and sometimes were seen within vesicles in the nucleoplasm
(fig. 4). In some cases, aggregates of particles, about 38 nm in diameter and
resembling naked nucleoids, appeared to be developing within the nucleus
from a localised "cloud" of fine granular material (fig. 5). Budding of virus
through the nuclear membrane was not observed, although suggestive out-
pocketings were occasionally seen (fig. 3). Cytoplasmic particles were not
observed.

Two cultures showed, in addition to cells containing formed virus, a few
cells whose nuclei contained long double-walled tubules about 74 nm in width.
The inner walls of the tubule showed traces of beading and measured 35 nm
in diameter. They invested a central, less dense core, which was occasionally
exposed as a thread about 22 nm thick. These tubular structures were invari-
ably associated with single-enveloped virus particles and, where they were cut
across, were obviously similar in structure to the latter (fig. 6).

In a number of other cultures, cells that were possibly monocytes were
found to contain linear arrays in the cytoplasm. These arrays were composed
of pairs of rather ill-defined membranes 37 nm apart, which invested a double
row of particles spaced at 15 nm intervals. Each doublet enclosed an electron-
lucent core about 10 nm in diameter. Parallel arrays produced a pattern
resembling a tyre-track, and often traversed practically the whole width of a
cell, deeply dividing the nucleus in the process (fig. 7). The membranous
component was more prominent when bundles of arrays were cut tangentially.
Some "tracks" appeared to be within the nucleus, but were in fact lying in
deep invaginations of the nuclear membrane (fig. 8). Sheets of similar struc-
tures were observed in the cytoplasm of a kidney cell from an infected mono-
layer (fig. 9).

Unlike the tubular structures, these "tyre-tracks" were never found in
transformed cells, although other transformed cells in the same culture
contained herpes-type particles. Other notable features were the frequent
proximity of centrosomes to the "tyre-tracks" and the occasional occurrence, pointed out to us by Mr M. Maxwell, of "tyre-tracks" in fresh, uncultured cells from certain clinically normal birds from the same flock. These birds are being further investigated for the presence of virus in cultured lymphocytes. A few clinically normal birds, belonging to the group in which Marek's disease was endemic, were observed to have virus in transformed cultured lymphocytes. In those cases in which further samples of lymphocytes were cultured, virus was again demonstrated. One bird was studied over a period of 12 mth and its lymphocytes were cultured on six occasions. Virus was observed each time. Serum from this bird contained antibodies to the Marek's disease antigen as demonstrated by indirect immunofluorescent staining of infected cultures, and virus was isolated from the lymphocytes in cultures of uninfected chicken kidney tissue. At the time of writing, this bird remains clinically normal.

Virus was not found in cultured lymphocytes from a number of birds which, though thought to be suffering from Marek's disease, failed to provide evidence of infection on post-mortem examination.

Cytochemical and immunological tests. Transformed lymphocytes stained with the fluorochrome, coriphosphine O (G. T. Gurr, Ltd), gave positive reactions for nuclear DNA in the cytoplasm. This was supported by the results of applying the methyl green-pyronin method of Kurnick. The indirect immunofluorescence test performed with sera from chicks naturally or experimentally infected with Marek's disease, and suitably controlled, showed antigenic material in a proportion of transformed cells, and in the "rosettes". As with the cytochemical tests, the reactive component was situated not only within the nucleus, where it was either diffuse or particulate, but also diffusely within the cytoplasm (figs. 10 and 11). Positive results were obtained in tests in which the first application was done with antiserum either from the classical or the acute form of Marek's disease. Control tests were done by substituting sera from disease-free birds, or infectious laryngotracheitis antiserum, and gave negative results.

Kidney cell cultures

A cytopathic effect identical with that described by Churchill and Biggs (1967), Solomon et al., and Witter, Solomon and Burgoyne (1969), was produced by culturing kidney cells from birds in a flock endemically infected with classical Marek's disease. These monolayers showed cytopathic effects after culturing for 3–8 wk. Alternatively, whole blood, lymphocyte suspensions (fresh or cultured) from classical cases and tumour cells from acute Marek's disease were inoculated on monolayers of uninfected kidney cells. The tumour cells were prepared by the same method as used for the trypsinisation of the kidney cells.

The cytopathic effect produced by infection of a healthy monolayer was usually visible within 3 wk. It was a necrotic reaction, with microplaques steadily increasing in size and becoming surrounded by large refractile polymicrocytes. Long delicate cytoplasmic threads extended across the plaque (fig. 12). After passage of infected cells removed from the glass with 0·1 per
cent. trypsin in a 1 in 5000 solution of versene, many plaques became apparent within 3–5 days at the third pass. The cytopathic effect observed in the culture of the kidney cells from birds already infected was somewhat different, in that there was less evidence of microscopic necrosis of the monolayer. Plaques of large round refractile polykaryocytes were seen apparently lying on the monolayer. These tended to disappear after 3–7 days, leaving a clean culture at the site, with or without the loss of continuity of the monolayer. On one occasion, the culture, after exhibiting one plaque at 3 wk, became free from plaques by 8 wk. After its establishment as a secondary culture, with production of a satisfactory monolayer, a typical cytopathic effect with extensive necrosis developed at 10 days, and there was complete destruction of the monolayer by 15 days. Electron microscopy showed many intranuclear particles.

Typical herpes (Cowdry’s type-A) inclusions were present in many cells bordering the plaques, in polykaryocytes and in the isolated cells lying along the cytoplasmic threads that spanned the space produced by the cytopathic effect (fig. 13). These inclusions all fluoresced brightly, as for DNA, with coriphosphine O, and indirect immunofluorescence tests showed that they contained antigens characteristic of Marek’s disease (fig. 14).

**DISCUSSION**

In previous electron-microscope studies of the tissues of birds suffering from Marek’s disease, no herpes-type virus has been observed (Wight et al., 1967). However, Schidlovsky, Ahmed and Jensen (1969) saw a herpes-type virus in material freshly processed for electron microscopy; this virus was present in the cytoplasm of the epithelium of the proximal renal tubule, although no virus was found in adjacent invading lymphoid tumour cells. Virus-like particles have been observed in cytoplasmic vacuoles of uncultured lymphocytes and in plasma from cases of Marek’s disease (Wight et al.; Glaser et al., 1969). They appeared to be RNA viruses, possibly belonging to the sarcoma-leucosis group, and their role in Marek’s disease is uncertain.

In our study, a herpes-type virus was observed in the nucleus in a proportion of transformed lymphocytes (“blast” cells) from proven cases of acute or classical Marek’s disease, after 3–5 days’ culture in vitro. Similarly, a virus was found in cultured lymphocytes from a few clinically normal birds from the same flock. These viruses were shown to be similar in morphology, antigenicity and nuclear staining properties to those isolated in cultures of chicken kidney tissue. The lymphocyte cultures were still infectious to chicken kidney tissue culture after several days’ incubation.

Why the virus cannot be observed in uncultured material is not readily explicable. However, some observations made in vitro suggest that this lack of success may be due to failure to examine the right cells. Culture of lymphocytes in the presence of phytohaemagglutinin leads to transformation of a proportion of cells to “blast” cells. This process involves a period of intense synthesis of protein and nucleic acid followed by an increase in size of the cells to two to four times that of other lymphocytes. Similarly, in tissue-culture
studies it appeared that passage of infective cells, or induction of a secondary culture, may be required for the virus associated with Marek's disease to become active and induce a cytopathic effect. Perhaps, in the latent stages of non-proliferating infected cells, the production of viral nucleic acid or viral protein is reduced or absent, and reappears only when the cells enter a stage of intense activity prior to mitosis. This would explain why monolayers appear to show recovery to primary infection, and why one monolayer, after 8 wk in culture, developed an extensive cytopathic effect 10 days after its establishment as a secondary culture.

There is no indication in what form the virus exists within the host. The transformed cells may have been infected at the time of sampling, or have become secondarily infected from another cell, such as a macrophage. The satellite phenomenon suggested that the central infected cell was a macrophage and that this was surrounded by small lymphocytes. Observations on poliovirus infection of transformed human lymphocytes indicate that monocytes are normally infected and lymphocytes become infected only after transformation (Willems, Melnick and Rawls, 1969). It is not known whether only those cells that are transformable possess the viral genome, but certainly no untransformed cultured lymphocytes demonstrated specific immunofluorescence. The reaction of these cells with chicken antiserum to Marek's disease implies that they possessed antigens that were foreign to the host and appeared to be identical with those carried by infected cells in chicken kidney tissue cultures.

In birds, there is firm evidence that there are two populations of lymphocytes, those dependent on the thymus and those dependent on the bursa of Fabricius. The former cells are concerned with rejection of grafts and the latter with the production of antibody and the development of delayed-type hypersensitivity (Glick, Chang and Jaap, 1956; Mueller, Wolfe and Meyer, 1960; Warner and Szenberg, 1964). Whether both types of lymphocytes can be transformed and demonstrate virus is not known. However, it has been reported that bursectomy and X-irradiation can ameliorate, but not completely prevent, Marek's disease, whereas thymectomy combined with irradiation has no effect. Further evidence for both a bursal and a thymic role in Marek's disease comes from the observation that affected birds have a defective humoral antibody response and a defective ability to reject skin grafts (Chubb and Churchill, 1968; Purchase, Chubb and Biggs, 1968; Biggs et al., 1969; Churchill, Payne and Chubb, 1969).

It is possible that the satellitosis of lymphocytes in cell cultures is a manifestation of an altered immunological response. The enlarged cell, which is the focus of this phenomenon, was shown to contain antigenic material by the indirect immunofluorescence test. Early "rosette" formation showed the presence of antigen in this type of cell only. Later stages showed fluorescence throughout the investing cells, indicating active spread or diffusion of antigenic material to the reacting lymphocytes. Whether the virus can complete its development in these cells is not known. It has proved difficult to establish whether rosettes form in cultures of lymphocytes from virus-free birds (Naspitz
and Richter, 1968). Preliminary tests showed reduced rosette formation or none in 90-hr cultures of lymphocytes from a small number of chickens that were reared in isolation and were free from clinically apparent Marek’s disease. One culture, however, did develop plentiful rosettes, and electron microscopy showed that herpes-type particles were present in transformed cells. It is interesting that this bird developed Marek’s disease some 8 wk after transfer to other premises.

The characteristic infiltration of lymphocytes and plasma cells into peripheral nerves in the neural form of the disease could also be interpreted as an immunological response, perhaps to a basic protein liberated in the nerve as a result of the destruction of myelin by the infective agent. This destruction has been shown to take place before the infiltration with lymphocytes (Heald et al., 1964). Reports that neurilemmal cells show proliferative changes in Marek’s disease (e.g., Sevoian and Chamberlain, 1964) indicate some form of participation by these cells. An auto-immune basis for Marek’s disease is, moreover, suggested by the similarity of some types of nerve lesion to those described by Siller (1960) in his study of experimental allergic encephalomyelitis in chickens.

Nature of the tubules and filamentous arrays

The obvious similarity in morphology and dimensions of the cross-sections of the intranuclear tubular structures to free, single-enveloped virus particles, and their close association with the latter, leaves little doubt that they are a filamentous form of the herpes-type virus. Similar structures have been described in connexion with other herpes-viruses, notably those of infectious laryngotracheitis of chickens (Watrach, 1962) and those of the renal carcinoma of leopard frogs (Stackpole and Mizell, 1968).

The construction of an icosohedral capsid invested with capsomeres requires the manufacture by the infected cell of both hexagonal and pentagonal capsomeres, 12 of the latter being essential for the formation of the 12 vertices. If, through a coding defect, only hexagonal capsomeres are formed, then flat sheets or tubular structures will result. An even more abortive attempt to assemble virus in the cytoplasm may be represented by the “tyre-tracks.” Their structure is basically similar to the inner portion of the tubular form of the virus, with reasonable agreement in the size of the various components. Fig. 15 represents an hypothetical reconstruction of the tubular form and shows how the inner part, divested of its outer coat, would present upon longitudinal median section an appearance similar to a “tyre-track.” Comparable structures have recently been reported in the proximal renal tubule epithelial cells of several species of monkey by Bulger (1968). She describes them as “granule-lamella complexes” and suggests they are arrays of ribosomes. Somewhat similar structures have been seen in the vascular endothelium of frogs (Stehbens, 1965), in taste-bud cells of rats (Farbman, 1967) and in the cortical cells of a human adrenal adenoma (Hoshino, 1969). These authors consider the structures to be essentially a ribosomal-lamellar complex, although they all mention the possibility that they may be of a viral nature. It may be significant that
three of the animal species involved, man, monkeys and frogs, are all known to be commonly infected with herpes-type viruses.

It is difficult to correlate the presence of structures in the cytoplasm with the replication of a herpes-virus that appears to be confined to the nucleus. A possibly similar structure was observed in skin epithelial cells of chickens infected with fowlpox virus, which never occurred in cells lacking this virus. However, this structure was not considered to be involved in the morphogenesis of fowlpox virus and its presence could not be correlated with the virus replication cycle (Simpson, 1969). Apparently no attempt was made to exclude the possibility of the cells also being infected with Marek’s disease virus.

One other possible explanation of the arrays remains to be considered. Centrosomes have frequently been seen in their vicinity. Are the arrays aberrant cilia? Most non-ciliated cells are now known to have the potential to form cilia in abnormal conditions, but the structure of the arrays is so entirely different from that of cilia that it would be difficult to interpret them even as highly aberrant structures of that nature.

**SUMMARY**

Electron microscopy of short-term cultured blood lymphocytes from spontaneous cases of "classical" (neural) Marek’s disease and some clinically normal chickens from the same flock showed a herpes-type intranuclear virus in a high proportion of transformed cells. In a few instances virus particles were closely associated with intranuclear filaments, which were thought to represent the product of aberrant viral replication. Some non-transformed cells showed granule-lamellar arrays in the cytoplasm, thought possibly to represent the inner structure of the filaments.
The addition of cultured lymphocytes to healthy chick kidney monolayers induced a typical transmissible cytopathic effect associated with nuclear inclusions. Similar results were obtained using fresh lymphocytes, or tumour cells, from cases of the "acute" disease. A spontaneous cytopathic effect often developed in monolayers prepared from clinically normal chickens in a flock in which the disease was endemic.

Indirect immunofluorescence tests with either classical or acute Marek's disease antisera indicated the presence of viral antigen in a high proportion of transformed lymphocytes and in the kidney cells in the region of the cytopathic effect.

A herpes-type virus was also demonstrated in cultured transformed blood lymphocytes in cases of acute Marek's disease with gonadal tumours.

This investigation has been supported by the British Empire Cancer Campaign for Research. We would also like to thank Mr M. Maxwell for technical assistance, and Mr J. H. R. Campbell for preparing fig. 15.
