An experimental evaluation of the pharmacokinetics of fusidic acid in peritoneal dialysis

LOUISE ROWE, GLENNE FINDON and T. E. MILLER*

University of Auckland, Auckland, New Zealand

Summary. Fusidic acid, an antimicrobial agent with activity against coagulase-positive and coagulase-negative staphylococci, has considerable potential for the management of staphylococcal peritonitis associated with continuous ambulatory peritoneal dialysis (CAPD). Whether fusidic acid reaches therapeutic levels in the dialysate once therapeutic serum levels have been achieved is not known. An animal model of CAPD that reproduced essential features of the clinical procedure was used to investigate this issue. Although oral administration was the preferred route, fusidic acid is not absorbed from the gastrointestinal tract of laboratory rats, and a subcutaneous injection of diethanolamine fusidate was used to achieve serum levels of the agent equivalent to those achieved clinically in man. In this model, fusidic acid concentrations up to 28 times the MIC for staphylococci were found in the dialysate when therapeutic levels of the agent were reached in the serum. The data provide support for continued experimental and clinical evaluation of the role of fusidic acid in CAPD-associated peritonitis.

Introduction

Staphylococcal peritonitis is a well recognised complication of continuous ambulatory peritoneal dialysis (CAPD). A frequency of 1.0–1.6 episodes of peritonitis/patient year has been reported from most large and multi-centre groups, although incidences outside the range often occur.3,4 Staphylococcal infection currently accounts for 65–75% of reported cases of peritonitis and of these, 30% are caused by the coagulase-negative staphylococcus, *Staphylococcus epidermidis*. Although several potentially effective antibiotics are available, few parenteral or orally administered antibiotics achieve therapeutic levels in the dialysate3–6 and antimicrobial therapy usually involves intraperitoneal instillation of the agents. Currently, vancomycin, together with an aminoglycoside or a broad-spectrum cephalosporin are commonly used. However, even with appropriate antimicrobial therapy, persistent peritonitis, defined as a lack of clinical improvement after 3–5 days of treatment, is observed in 5–15% of peritonitis episodes and accounts for 25–60% of the drop-outs from CAPD programmes.7 Of CAPD-related deaths, >15% have been attributed to this infection and experienced centres have reported the risk of dying from a peritonitis episodes to be >2%/8.

Therefore, there is a need for continued assessment of new or existing agents that may offer specific advantages over current protocols. Fusidic acid is one such agent. It is highly active against coagulase-positive and coagulase-negative staphylococci. Resistance to it, which is chromosomal in nature, may develop but does not appear to be a problem in clinical practice.9,10 It is well absorbed after oral administration, leading to serum levels of 15–30 mg/L, well in excess of the MIC for staphylococci of 0.03–0.25 mg/L.11 Fusidic acid is also widely distributed in tissues giving high concentrations in such diverse sites as sputum,12 synovial tissue,13 mucus,14 bone15 and pus.16 Whether fusidic acid reaches therapeutic levels in the dialysate after oral administration is, however, unknown. In the present study, an animal model of CAPD was used to investigate this issue.

Materials and methods

Animals

Adult female Dark Agouti (DA) rats weighing 180–250 g were obtained from an inbred colony.

CAPD model

Rats were anaesthetised and two vertical incisions were made, one 3.0 cm in length through the right abdominal wall and the second, subcutaneously 0.5 cm long between the ears. A stainless steel trochar was...
Fed through the head incision, under the skin and pushed between the skin and muscle layer across the ribcage, before piercing the abdominal muscle and entering the peritoneal cavity. The end of a 15-cm length of Silastic® medical-grade tubing (Dow Corning Corporation, Michigan, USA; catalogue no. 601-325) was placed over the end of the cannula and anchored with a suture (4-0 TI.Cron, Davis & Geck, Gosport, Hants) loosely wound around the cannula between the two collars and secured to the abdominal muscle. The abdominal incision was then closed. A 1-cm cube of foam with a central 5-mm hole was pushed over the cannula at the head end and glued in place. This was then placed under the skin to secure the tube and the incision was closed before another Silastic collar was pushed over the external cannula. Finally, a cap 5 mm long was fitted into the cannula, sealing the opening. Animals were treated prophylactically with 5 mg of ciprofloxacin (intravenous infusion; Bayer New Zealand Ltd, Auckland, New Zealand) via the catheter at the time the cannula was inserted and again over the next 2 days to eliminate post-operative infection. Dialysis was performed on lightly anaesthetised animals with warmed Dianeal PD-2 (Travenol Laboratories Inc., Deerfield, USA) which was introduced into the peritoneum through the permanent indwelling cannula.

**Fusidic acid administration**

Fusidic acid (Fucidin; Leo Pharmaceutical Products, Ballerup, Denmark) was given to rats by the oral, intramuscular (i.m.) or subcutaneous (s.c.) route, at doses of 20–200 mg/kg. Oral administration was with either crushed tablets or the oral suspension. For i.m. and s.c. treatment, a solution of intravenous diethanolamine fusidate was used. The i.m. dose was given in the thigh muscle and the s.c. dose in the loose skin of the back of the neck.

**Experimental procedure**

Two groups of animals, one with a cannula in place and the other non-cannulated, were adapted to dialysis by the daily intraperitoneal (i.p.) administration of 20 ml of warmed Dianeal 1.5%, for 3 days before they were given fusidic acid. On the fourth day, fusidic acid was administered shortly before the i.p. administration of 20 ml of warmed Dianeal 4.25%. The latter concentration of Dianeal had been found to cause fluid retention in the peritoneal cavity as happens in clinical dialysis in man. Blood samples were collected 0, 5, 1, 2 and 4 h later from the tail vein of lightly anaesthetised animals. The serum was separated and stored at −70°C until analysed. Gentle abdominal massage was done before sampling to mix peritoneal contents.

**Effect of sterile inflammation.** To determine the effect of the local inflammatory response on fusidic acid levels in the peritoneal cavity, a sterile reaction was induced with sodium caseinate before the administration of the antibiotic. Sixteen animals (non-cannulated) were divided into two groups. One group was given 20 ml of Dianeal 1.5% daily for 3 days and on the fourth day, 20 ml of Dianeal 4.25% was given at the same time as the fusidic acid was administered. The second group was also dialysed with 20 ml of Dianeal 1.5% on day 1, but on days 2 and 3, 12 ml of Dianeal 1.5% and 8 ml of sodium caseinate 6% were introduced; on day 4, 20 ml of Dianeal 4.25% was given simultaneously with fusidic acid. Blood and peritoneal dialysate samples were taken from individual animals 1 and 2 h after fusidic acid administration respectively.

**Biological assay for fusidic acid**

Fusidic acid was assayed by the agar-diffusion technique with a clinical isolate of *S. aureus*, sensitive to fusidic acid, as the test organism. The test strain was grown overnight in nutrient broth and 1 ml of a 1 in 10 dilution of the culture in saline was added to 120 ml of casamino acid-yeast extract agar at 47°C. This was poured into a 23 × 23-cm assay plate and allowed to solidify. A cork borer was used to punch out 7-mm diameter wells in the agar. A standard solution of diethanolamine fusidate (DEF) containing 200 mg/L was serially diluted in serum citrate phosphate diluent or Dianeal to achieve concentrations of 0.15–10 mg/L. These standards, each assayed in triplicate, were used to construct the standard curve. A serum and Dianeal sample, each containing DEF 20 mg/L, were assayed as additional controls with each experiment. Serum samples were diluted 1 in 4 and 1 in 8 with serum citrate phosphate buffer and the peritoneal fluid samples were assayed undiluted; 60 μl of each dilution, the standards and controls were added to the appropriate wells. Plates were incubated on a flat surface overnight at 37°C and the zones around each well were measured with digimatic callipers (Mitutoyo Inc., Japan). The values of each sample were determined from the respective standard curve, adjusted for the dilution factor, and the level of diethanolamine fusidate obtained was converted to the equivalent concentration of fusidic acid.

**Cytology**

A total white cell count in acetic acid 2% was done in a Neubauer haemocytometer (American Optical Corp., NY, USA). Differential cell counts were made on a cytocentrifuge preparation (Shandon Southern, Runcorn, Cheshire) of a sample of dialysate, diluted in Hanks’ Balanced Salts Solution to give approximately 2 × 10⁵ cells/ml and stained with Leishmans’ stain.
Statistical analysis

Results were evaluated by the non-parametric Wilcoxon sum of ranks test.

Results

Fusidic acid administration

Oral administration of the tablet formulation and oral suspension of fusidic acid to DA rats in doses up to 200 mg/kg failed repeatedly to achieve fusidic acid serum levels of therapeutic significance (<0.1 mg/L). Intramuscular injections of diethanolamine fusidate (100 mg/kg) gave fusidic acid levels up to 20 mg/L, but adverse effects, including hindlimb weakness and necrosis, precluded further use of the route. However, subcutaneous administration, achieved levels and a pharmacological profile similar to those found in clinical use. Mean fusidic acid concentrations of 14 and 15 mg/L were observed 30 and 60 min after a single dose of 200 mg/kg was administered s.c. Side effects were limited to lesions at the site of injection. Repeated administration of this dose by the s.c. route over a 4-day period, did not lead to increased serum levels of fusidic acid (fig. 1).

Fusidic acid levels in the peritoneal cavity

Non-cannulated animals. The relationship between serum fusidic acid levels and the concentration of the agent in the dialysate was first studied under experimental conditions uncomplicated by the presence of an indwelling cannula. Animals were conditioned to the protocol by daily instillation of 20 ml of warmed 1.5% dialysate fluid into the peritoneal cavity for 3 days before the administration of the agent. On the fourth day, diethanolamine fusidate 200 mg/kg was injected s.c.; at the same time, 20 ml of 4.25% dialysate was given. Mean peritoneal fluid levels of 1.6 SD 0.9, 2.6 SD 1.2, 4.3 SD 1.6 and 3.6 SD 2.3 mg/L were found 0.5, 1, 2 and 4 h, respectively after administration. There was no evidence of an increase in the fusidic acid level in the dialysate when multiple doses (200 mg/kg, three times daily for 2 days, followed by a single dose on the third day) were given. In the latter case, mean levels of 1.1 SD 0.67, 2.4 SD 1.2, 2.3 SD 1.4 and 1.1 SD 0.77 mg/L were obtained after similar time intervals (fig. 2).

Dialysate: serum fusidic acid ratio. In the previous experiments (figs. 1 and 2), serum and dialysate samples were obtained from two different groups of animals to reduce the stress of repeated sampling. In this experiment, the ratio of fusidic acid levels in the serum and dialysate was determined in individual animals. A protocol was used whereby animals were bled 1 h after diethanolamine fusidate administration and were then killed after 2 h to obtain a sample of peritoneal fluid. After a single s.c. dose of diethanolamine fusidate 200 mg/kg, serum levels varied between 3.89 and 31.0 mg/L (fig. 3a). The ratio of dialysate to serum fusidic acid concentrations were in the range 6.4–24.5%, mean 15 SD 7%, in the 12 animals studied. After multiple doses (200 mg/kg three times daily for 2 days, followed by a single dose on the third day), serum levels of fusidic acid were between 3.8 and 36.0 mg/L (fig. 3b). Ratios of 8.6–38.5%, mean 21 SD 9–6% were obtained.

Fusidic acid levels in cannulated animals. The pharmacokinetics of fusidic acid transfer across the peritoneal membrane was examined in cannulated rats. A conditioning period and experimental protocol similar to that used in the non-cannulated animals was followed; the indwelling cannula was used to deliver dialysate into and out of the peritoneal cavity. A single s.c. dose of 200 mg/kg resulted in mean fusidic acid levels...
concentrations in the peritoneal fluid of 0.14 SD 0.16, 0.43 SD 0.30, 0.89 SD 0.88 and 1.8 SD 1.7 mg/L respectively, 0.5, 1, 2 and 4 h after administration. Multiple dosing gave average levels of 0.76 SD 0.49, 0.63 SD 0.24, 1.4 SD 0.62 and 1.1 SD 0.37 mg/L at the equivalent sampling times (fig. 4).

Inflammation and fusidic acid pharmacokinetics

Effect of cannulation. Experiments were done to determine the effect that implanting a foreign body might have on inflammatory mechanisms in the peritoneal cavity. Saline, and Dianecol 1.5 and 4.25% were added to the peritoneal cavity of animals with and without indwelling cannulae and samples were taken immediately and 2 and 4 h later for leucocyte counts. Apart from a response to saline 4 h after instillation, non-cannulated animals showed little response to the two dialysis solutions. However, when saline was introduced into the peritoneal cavities of cannulated animals, a 17-fold increase in total leucocyte numbers occurred; similarly, there was a noticeable response to the two Dianecol solutions (table).
Serum levels of fusidic acid in the animals in which sterile inflammation was induced by administration of sodium caseinate were significantly lower than in their control group (2.9 SD 0.54 vs 3.8 SD 0.72 mg/L, p = 0.01), and resulted in a substantial increase in the peritoneal fluid to serum ratio in these animals (8% vs 28%) (fig. 5).

Discussion

This study was done to determine whether serum levels of fusidic acid equivalent to clinically achieved levels in man would, in a rat model of CAPD, be associated with therapeutic levels of the agent in the dialysate. The stimulus for such an investigation arose from the continuing need to evaluate agents with therapeutic potential in the management of staphylococcal peritonitis associated with CAPD. Although studies of this nature are best done with clinical material, ethical constraints commonly demand that proposals for clinical investigations be supported by laboratory data from animal models.

The model of CAPD used in these experiments simulated the essential features of the procedure in man. Daily dialysis over a 21-day period had no effect on biochemical or haematological parameters and animals maintained body weight and remained alert and active over this period (unpublished observations).

Initial attempts to use the oral route for the administration of fusidic acid were unsuccessful because the agent did not appear to be absorbed and could not be demonstrated in the serum. However, s.c. injection of diethanolamine fusidate resulted in levels of fusidic acid in the serum equal to those we had hoped to achieve by oral administration. When the procedure was used to obtain serum levels equivalent to those achieved clinically in man, the administration of a single dose of diethanolamine fusidate gave fusidic acid concentrations in the dialysate of 6–24% of the serum levels. This concentration was 4–28 times the MIC for staphylococci (0.03–0.25 mg/L).

Determination of dialysate to serum ratios in animals given multiple doses of fusidic acid gave similar results. One additional finding of interest was the increase in dialysate to serum ratio of fusidic acid in animals with an experimentally induced sterile peritonitis. Few studies have examined intraperitoneal antibiotic kinetics during peritonitis and most therapeutic protocols are based on drug kinetics across the normal

* After instillation of 20 ml of saline, or Dianal 1.5 or 4.25%.
shows non-linear characteristics leading to greater than expected maximum serum concentrations. With MIC values of 0.03–0.25 mg/L for both *S. aureus* and *S. epidermidis*, including the β-lactamase producing strains, and serum concentrations reaching levels up to 100 times the latter figures, good responses have been obtained in several staphylococcal infections which, generally, have been difficult to treat.

The agent appears to penetrate into relatively inacces-
sible sites, and could be useful in eliminating *S.
epidermidis* embedded in dense accumulations of
extracellular slime on the peritoneal catheters. Other
useful characteristics in patients with compromised
renal failure include the findings that only a small
amount of the antibiotic is excreted by the kidney in
an active form and that there is no demonstrable cross-
resistance between fusidic acid and other antibiotics.

The ability of an antibiotic to penetrate into the
extravascular tissues and body spaces is governed by
several factors, including the concentration gradient
from serum to tissue, binding to proteins in serum and
tissue, molecular size, pK value and lipid solubility.
Pharmacokinetic profiles based on the chemical
characteristics of individual agents are not always
accurately predictive, as, for example, the finding that
protein-bound cephalosporins such as cephalexin and
cefazolin achieve concentrations in the peritoneal
cavity similar to those of the poorly bound aminoglycosides. Our current observation that clinically
effective serum levels of fusidic acid are associated
with therapeutically useful levels of the agent in the
dialysate during CAPD in rats, suggests that, although
highly protein bound, other compensating factors act
to release a pool of antibiotic as the protein content of
the milieu decreases.

The data obtained with the animal model of CAPD,
demonstrating that therapeutic serum levels of fusidic
acid were associated with potentially effective concen-
trations of the agent in the dialysate, have provided a
firm basis for further laboratory, experimental and
clinical studies. These will help to determine the role
of fusidic acid in the management of staphylococcal
peritonitis, commonly associated with this procedure.
Further experiments are clearly warranted to assess
the ability of the agent to contain experimentally-
induced staphylococcal peritonitis. Clinical studies
will also be required to confirm the experimental data
and evaluate the efficiency of the agent in man during
therapeutic CAPD.
