Summary. The purpose of this study was to clarify the association between the oral infectivity of a bacterial strain and its susceptibility to ingestion by mononuclear phagocytes or ability to survive within them. Ten bacterial strains tested—all of known oral infectivity—comprised Salmonella typhimurium, Listeria monocytogenes (three strains), Escherichia coli (two strains), Proteus mirabilis, Enterococcus faecalis, Bacteroides fragilis, and a Bacteroides sp. The phagocytic uptake of each strain was measured as the bacteria to phagocyte ratio after mononuclear phagocytes in mouse peritoneal exudate were permitted to ingest bacteria in vivo for 3 min. The three Listeria strains were the most susceptible to phagocytic uptake and the Salmonella strain was relatively resistant. The intracellular survival of each strain was studied during a subsequent 2 h in-vitro incubation of the mononuclear phagocytes that had been permitted to ingest bacteria in vivo. The strains with the best intracellular survival were Ent. faecalis and two of the three Listeria strains. The ability of S. typhimurium to survive intracellularly was intermediate but better than that of the two E. coli strains. Oral infectivity was not consistently correlated with susceptibility to ingestion by mononuclear phagocytes or ability to survive within them.

Introduction

Different species or strains of enteric bacteria vary in invasiveness.1-2 Pathogenic organisms such as Salmonella spp. and Listeria monocytogenes given by the natural (oral) route are able to migrate ("translocate") from the intestine to other sites, such as the liver and spleen, and cause systemic disease.3-6 Translocation of potentially pathogenic members of the normal intestinal microflora, such as Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa and Enterococcus faecalis, can be induced by bringing about intestinal overgrowth. This has been studied in gnotobiotic mice and in antibiotic-treated rodents colonised with an antibiotic resistant strain.7-8 Normal animals are resistant to overgrowth and to translocation of such bacteria given orally, even in large doses.13-14,16,18 Relatively non-pathogenic, strictly anaerobic members of the normal intestinal flora such as Bacteroides spp. can rarely be induced to translocate, even in gnotobiotic mice with high intestinal concentrations of the organism.7-8 or in antibiotic-treated rodents with intestinal overgrowth of an antibiotic resistant strain.17 Earlier studies showed that mononuclear phagocytes could transport inert particles (1 μm latex beads) and possibly viable bacteria from the intestinal lumen to the draining mesenteric lymph node (MLN).19 A similar mechanism of particle transport had been described for alveolar macrophages migrating from the terminal alveolus of the lung to the draining tracheobronchial lymph node.20 Because Salmonella spp. and L. monocytogenes can survive and possibly replicate in phagocytic leukocytes,21-43 and because they readily translocate from the intestine, it seemed reasonable to speculate that facultative intracellular parasitism is associated with oral infectivity.

Thus, the aim of this study was to determine if the oral infectivity of a bacterial strain was related to the susceptibility of that strain to ingestion by mononuclear phagocytes or its ability to survive within them.

Materials and methods

Mice

Female Swiss Webster mice (18–22 g; Harlan-Sprague Dawley, Inc., Indianapolis, IN, USA) were used in all experiments.

Bacteria

Bacterial strains were chosen for their strong or weak ability to produce systemic infection in orally

*Before oral inoculation with E. coli C25 or B. fragilis 9032, mice were treated for 3 days with bacitracin and streptomycin or penicillin and neomycin, respectively.
†Indigenous caecal bacteria (streptomycin-sensitive E. coli or an Enterobacter sp.) were also recovered (10–80 bacteria/MLN) from four of 24 saline-treated mice, four of 22 E. coli-treated mice, and two of 19 B. fragilis-treated mice.
‡E. coli C25 was enumerated on MacConkey agar supplemented with streptomycin 100 µg/ml, and B. fragilis 9032 on bacteroides bile esculin agar. Caecal organisms from control mice gave negligible growth on these media.
§Significantly increased compared to the other two treatment groups (p < 0.001).
| Significantly greater than in mice given B. fragilis 9032 (p < 0.001). |

Polytechnic Institute and State University, Blacksburg, VA, USA. E. coli C25, a streptomycin-resistant, human clinical isolate, was obtained from Dr R. Berg, Louisiana State University, Shreveport, LA, USA; this strain has been widely used in studies of bacterial translocation in rodents.6–8,11,16 The remaining strains were isolated from Swiss Webster mice during studies of intestinal bacterial translocation in our laboratory.6–8,11,16 All bacterial strains were maintained at −70°C in Brain Heart Infusion Broth (Difco) cultures were diluted in phosphate-buffered saline (PBS) 10%, except the Bacteroides strains which were maintained at −70°C in Cooked Meat Broth.29

### Extracellular haemolysis production by L. monocytogenes

Production of extracellular haemolysin (listeriolysin) by L. monocytogenes was assayed by the method of Tabouret et al.29 with minor modifications. Filter-sterilised supernatants from 24-h Tryptic Soy Broth (Difco) cultures were diluted in phosphate-buffered saline supplemented with 6 mM cysteine hydrochloride, incubated for 30 min at 35°C to activate the haemolysin,30 mixed 9 parts to 1 part with washed sheep red blood cells (RBCs) 10%, incubated at 35°C for 30 min and centrifuged to pellet the RBCs; the degree of haemolysis was measured as the absorbance at 540 nm. Haemolytic units were expressed as the highest dilution of bacterial supernate showing 50% haemolysis.

**Oral infectivity of B. fragilis 9032, E. coli C25, S. typhimurium 14028 and L. monocytogenes + H1a, −H1a, + H4b**

In this paper, oral infectivity is defined as the ability of an organism to translocate to extra-intestinal tissues (MLN and liver) after oral inoculation. Separate groups of mice were inoculated orally, by means of a "feeding needle", with 0.1 mL of suspensions containing log$_{10}9$ saline-washed cells of B. fragilis, E. coli, S. typhimurium or L. monocytogenes (strain + H1a, −H1a, or + H4b). All bacterial cells were obtained from overnight tryptic soy broth cultures grown aerobically, with the exception of B. fragilis which was grown anaerobically in supplemented brain heart infusion broth. Control mice were inoculated with saline. To facilitate intestinal colonisation with streptomycin-resistant E. coli C25, mice were given drinking water containing bacitracin (Sigma) 2 mg/ml and streptomycin sulphate (Sigma) 2 mg/ml for 3 days before oral inoculation. To facilitate intestinal colonisation with penicillin-resistant B. fragilis 9032, mice were given drinking water containing penicillin G (Sigma) 200 units/ml and neomycin sulphate (Upjohn Co.) 4 mg/ml for 3 days before oral inoculation. Mice were killed 2 days after oral inoculation. In mice given antibiotics, the treatment was continued for the duration of the experiment. Viable bacteria in the caecum (tissue with contents), MLN and liver were counted and identified as previously described.13–16 For the selective isolation of the orally inoculated strains from the caecal flora, caeca were also plated as appropriate on listeria selective agar,21 MacConkey agar supplemented with streptomycin 100 µg/ml,15–18 or Bacteroides Bile Esculin Agar 28 (Difco). The limits of detection of the assays were 10 bacteria/MLN, 15 bacteria/liver, and 500 bacteria/caecum. The combined results of two separate experiments are presented (11–18 mice/treatment group in each experiment). MLN from all mice in all experiments were examined. Livers were examined from all mice in experiments with salmonella and listeria. The caecal microflora was characterised in three or four mice/treatment group in each of the two experiments.

**In-vivo phagocytic uptake and in-vitro intracellular survival of bacteria in mononuclear phagocytes**

Bacterial uptake and intracellular survival in mononuclear phagocytes were assayed by the method of...
Leijh et al.32 with minor modifications as described previously.33 Briefly, mice were given an intraperitoneal injection of 1 ml of proteose peptone 10% in tap water, and 48 h later an intraperitoneal injection (1 ml) of \( \log_{10} 8 \) saline-washed bacteria of a single strain, prepared as described for oral inoculation (above). After 3 min (the time of maximal phagocytic uptake33), mice were killed by cervical dislocation, and peritoneal exudate cells were harvested in ice-cold Hanks’s balanced salts solution containing gelatin 0·1%, washed at least four times (4 min, 110 g) in the same medium, and resuspended in 4 ml to a concentration of \( 7 \times 10^6 \) cells/ml. After the final wash, the numbers of bacteria in the supernates were 10–100-fold lower than the corresponding numbers of intracellular bacteria and, therefore, were unlikely to interfere with assay of the latter. As in previous reports,33-34 Wright-Giemsa stains demonstrated that c. 80% of the peritoneal exudate cells were macrophages, with \( \geq 95\% \) viability as determined by both propidium iodide and trypan blue dye exclusion. This preparation of peritoneal exudate cells will be termed mononuclear phagocytes for the purposes of the present report. Washed mononuclear phagocytes were agitated by rotation of the suspension at 4 rpm at 37°C for a maximum of 120 min. At various time intervals, a 0·5-ml sample was removed, mixed with 0·5 ml of ice-cold Hanks’s balanced salts solution and centrifuged for 4 min at 110 g; the cell pellet was then resuspended in 1 ml of bovine serum albumin (Sigma) 0·01% in ice-cold distilled water and subjected to lysis by three cycles of freezing and thawing in liquid nitrogen and warm (37°C) water. Complete lysis of phagocytes was verified microscopically. The numbers of viable intracellular bacteria were determined, after serial dilution in phosphate-buffered saline, by appropriate culture methods.35

At the initial time point in this assay (0 min), phagocytic uptake was measured by calculating the bacteria to phagocyte ratio ("phagocytic index").36 By the method of Leijh et al.,33 the rate constant \( (K_u) \) for in-vitro intracellular killing between 0 and 120 min was calculated as: \( K_u = \frac{\ln N_{t=0} - \ln N_0}{t} \) where \( N \) was the number of bacteria and \( t \) was the time in minutes.

Four points should be borne in mind. Firstly, the two anaerobic Bacteroides strains could be used in this assay despite the aerobic incubation because there was no loss of viability after exposure of either strain to atmospheric oxygen for 24 h. Secondly, the fate of intracellular bacteria had to be interpreted in a dynamic milieu in which phagocytes could still continue to ingest extracellular bacteria.3 Assessment of viable intracellular bacteria is reliable only when they exceed the extracellular bacteria by 10–100 times.38 Assay of intracellular bacteria was not possible after 120 min because the numbers of extracellular bacteria in the leucocyte supernates increased substantially, probably due to phagocyte degradation and liberation of viable bacteria, coupled with continued multiplication. In addition, the number of peritoneal exudate cells decreased by at least 50% from 120 to 240 min and the cell suspension began to stick to the sides of the test tube, presumably due to a release of leucocyte DNA. Thirdly, repeated centrifugation was used to decrease the numbers of extracellular bacteria in the leucocyte suspensions. Some investigators have used antibiotics to kill extracellular bacteria (e.g., gentamicin to kill extracellular listeria37-38), but we found, as have others,39-40 that gentamicin affected the viability of intracellular bacteria. Finally, adherent macrophages were not used because they might have decreased listericidal activity.41

**Scanning electronmicroscopy of peritoneal exudate cells**

Preparations of washed mononuclear phagocytes, containing viable intracellular bacteria, were viewed by scanning electronmicroscopy to determine if bacteria were adherent to the leucocytes. Washed mononuclear phagocytes were fixed in 0·1% cacodylate buffer containing glutaraldehyde 3%, dehydrated, critical-point dried with CO	extsubscript{2}, sputter-coated with gold palladium, and examined at 20 kV with a Hitachi S-450 scanning electron microscope.

**Statistical analysis**

Statistical analyses were performed with StatView SE+Graphics (Abacus Concepts, Berkeley, CA, USA). Bacterial numbers (\( \log_{10} \) transformed), phagocytic indices, and intracellular killing constants \( (K_u) \) were analysed by a one-way analysis of variance followed by Fisher’s test for least significant difference. Mice with no detectable bacteria in MLN or liver were not considered in computing the differences in the numbers of bacteria in these sites among various treatment groups. The frequency of bacterial recovery from MLN and liver was determined by \( \chi^2 \) analysis with continuity correction.

**Results**

**Quantitation of extracellular haemolysin production by listeria**

The haemolytic properties (see above) of the three strains of L. monocytogenes were confirmed by four separate assays, all of which showed 512, 256 and 32 units of extracellular haemolysin for strains \(+H1a, +H4b\) and \(-H1a\), respectively.

**Oral infectivity of S. typhimurium 14028 and L. monocytogenes**

Table II shows the caecal colonization and oral infectivity of S. typhimurium 14028 and L. monocytogenes \(+H1a, -H1a\) and \(+H4b\). Oral inoculation with \( \log_{10} 9 \) viable cells had little effect on the caecal...
Fig. 1. Phagocytic uptake of strains expressed as the number of viable intracellular bacteria/ml divided by the number of mouse peritoneal mononuclear phagocytes/ml (standardised to $7 \times 10^6$). Intracellular bacteria were obtained from phagocytes that had been permitted to ingest bacteria in vivo for 3 min. Each value represents the mean of 5-9 separate assays; bars are 95% confidence intervals. Significant differences ($p < 0.05-0.01$) occurred between any two strains that can be connected by a line that starts without an arrowhead and ends with an arrowhead. **Oral infectivity of B. fragilis 9032 and E. coli C25**

Table III shows the caecal colonisation and oral infectivity of B. fragilis 9032 and E. coli C25. Neither strain could be expected to colonise the caecum without the administration of antibiotic, or to translocate to the MLN in the absence of caecal overgrowth. Therefore, mice were treated with bacitracin and streptomycin to enhance caecal colonisation of E. coli C25 (table III) and induce caecal overgrowth. To compare the translocation of B. fragilis present in similarly high caecal concentrations, 36 mice were treated with neomycin and penicillin and the caecal concentration of B. fragilis was monitored in each animal. Although there was considerable animal to animal variation, 19 of 36 treated mice were colonised with B. fragilis at concentrations of $\log_{10} 9.8-10.9$ g of caecum. In these mice, translocation of bacteria to the MLN was, as expected, less striking than in animals colonised by E. coli (table III). In this experiment, the liver was not cultured because high caecal concentrations of E. coli or B. fragilis do not usually induce systemic spread.

**Uptake of eight strains of intestinal bacteria by peritoneal mononuclear phagocytes**

Fig. 1 presents the phagocytic index of eight strains of intestinal bacteria with varying oral infectivity (table I). L. monocytogenes - H1a was ingested more efficiently than the other strains; 1 ml of a suspension of peritoneal mononuclear cells ($7 \times 10^6$ cells/ml) contained an average of $\log_{10} 7.1$ listeria. S. typhimurium 14028 was one of the least efficiently ingested strains; 1 ml of mononuclear cell suspension contained an average of only $\log_{10} 5$ salmonella. The general observation was that phagocytic uptake (fig. 1) was not consistently correlated with oral infectivity (table I).

One ml of peritoneal mononuclear cell suspension contained an average of $\log_{10} 4.4$ and 4 of P. mirabilis and Bacteroides sp., respectively (n = 6). These data are not presented as phagocytic indices in fig. 1 because repeated centrifugation failed to produce a concentration of extracellular bacteria 10-fold lower than the corresponding concentration of intracellular bacteria. Therefore, we concluded that the phagocytic indices of...
Fig. 2. Percentage survival of strains of bacteria incubated in vitro with mouse mononuclear phagocytes for 0, 30, 60 and 120 min (mean values of 4-7 separate assays): — ○ — L. monocytogenes + H1a, ▲ — Ent. faecalis M20, — □ — L. monocytogenes — H1a, — ● — S. typhimurium 10428, — ▲ — L. monocytogenes + H4b, — ■ — B. fragilis 9032, — — ○ — E. coli M14, — — Δ — E. coli C25.

Fig. 3. Survival of strains incubated for 120 min in vitro with mouse mononuclear phagocytes. Survival expressed as the intracellular killing constant (K). Each value represents the mean of 5–9 separate assays; bars are 95% confidence intervals. Significant differences (p < 0.05–0.01) occurred between any two strains that can be connected by a line that starts without an arrowhead and ends with an arrowhead. Abbreviations as in fig. 1.

P. mirabilis and Bacteroides sp. could not be quantified with accuracy, but were lower than the phagocytic index of S. typhimurium. When the phagocytic uptake of this strain of P. mirabilis (M13) was studied previously with mice purchased from a different animal supplier, 1 ml of peritoneal mononuclear cell suspension contained an average of log₁₀ 4·8 P. mirabilis cells.³³

To verify that the washed peritoneal exudate cells did not contain adherent extracellular bacteria at the outset of the assay for intracellular survival, they were viewed by scanning electronmicroscopy. At least 200 leucocytes were observed for each bacterial strain tested. No adherent extracellular bacteria were seen except for P. mirabilis, 2–10 cells of which were seen adhering to one in 20 leucocytes.

Intracellular survival of eight strains of intestinal bacteria in peritoneal mononuclear phagocytes

The intracellular survival of eight bacterial strains is presented as the percentage survival after 0, 30, 60 and 120 min (fig. 2) and as the intracellular killing constant (K) during the period of 120 min (fig. 3). According to the formula for K, a negative value would indicate an increase in the numbers of intracellular bacteria, a

*Relative infectivity based on information in table I.
†Relative phagocytic uptake based on information in fig. 1 and reference 33.
‡Relative intracellular survival based on information in fig. 3 and reference 33.

result not observed with any of the strains tested. As shown in fig. 2, all strains decreased in number during the 120 min of this assay. Surprisingly, the three strains best able to survive intracellularly were *L. monocytogenes* + H1a and - H1a and *Ent. faecalis*, with > 60% of the intracellular bacteria persisting for 120 min (fig. 2). This result was reflected in correspondingly low Kc values (fig. 3). Another surprising result was that the Kc of *S. typhimurium* (a relatively virulent organism) was not significantly different from that of the relatively avirulent *B. fragilis*. The general observation was that intracellular survival (fig. 3) was not consistently correlated with oral infectivity (table I).

Because we could not eliminate sufficient numbers of extracellular bacteria, the intracellular survival of *P. mirabilis* and a *Bacteroides* sp. could not be accurately quantified. In a previous study,29 slightly more *P. mirabilis* were ingested than in the present study, permitting repeated centrifugation to remove sufficient numbers of extracellular *P. mirabilis* (i.e., resulting in 10-fold fewer extracellular *P. mirabilis* than intracellular bacteria). In this latter study, *E. coli* M14 was also tested, its intracellular survival being similar to that of *P. mirabilis* M13.

Discussion

The results showed (tables II and III) that pathogenic species, such as *S. typhimurium* and *L. monocytogenes*, could translocate after oral inoculation into mice; that facultative species, such as *E. coli*, translocated after antibiotic-induced intestinal overgrowth; and that strictly anaerobic species, such as *B. fragilis*, translocated only in an occasional mouse even after antibiotic-induced overgrowth. These studies of bacterial translocation were performed so that strains with a documented spectrum of oral infectivity could be tested for their ability to interact with mononuclear phagocytes. These results are summarised in table IV.

In studying the interactions between salmonella and macrophages, Wells and Hsu22 concluded that the virulence of salmonella strains was inversely related to the phagocytic index. *S. typhimurium*, a virulent strain in our study (table I), was relatively resistant to phagocytosis (fig. 1). However, *P. mirabilis* and a *Bacteroides* sp. were even more resistant to phagocytosis than *S. typhimurium*, yet these two strains were clearly less virulent than *S. typhimurium*. Curiously, *L. monocytogenes* strains + H1a, - H1a and + H4b, and *Ent. faecalis* had similar phagocytic indices (fig. 1), yet these strains differed in oral infectivity (table I). Therefore, the degree of bacterial phagocytosis by mouse mononuclear phagocytes was not correlated with oral infectivity in mice (table IV).

Because salmonellae and listeria translocate from the intestine with relative ease,4-6 we postulated that their ability to survive in mononuclear phagocytes31-33 might be associated with oral infectivity. None of the strains appeared to multiply in mouse mononuclear phagocytes, including the orally invasive *S. typhimurium* and *L. monocytogenes* + H1a (figs. 2 and 3). This is not an unusual observation. Czuprynski et al.43 used proteose peptone-elicited mouse macrophages in a similar antibiotic-free assay and observed that the numbers of viable intracellular *L. monocytogenes* decreased by c. log_10 0.5 in 2 h. Buchmeier and Heffron44,45 reported that *S. typhimurium* 14028 (the strain used in the present study) survived moderately well in splenic and bone marrow-derived macrophages, but less well in peritoneal macrophages (resident and proteose peptone-elicited). Hsu3 concluded that the pathogenesis of salmonellosis was unlikely to be directly related to the ability of the organisms to survive in host macrophages. Thus, our observations that salmonella and listeria did not survive efficiently (or multiply) in mononuclear phagocytes were consistent with those of others.

We expected that pathogenic *Salmonella* and *Listeria* strains would survive better intracellularly than species of the normal enteric microflora. This expectation was sometimes but not always fulfilled. Buchmeier and Heffron44 recently compared *S. typhimurium* 14028 with two *E. coli* strains and noted that it survived intracellularly and inhibited macrophage...
As did the cyrogenes comment seems appropriate. Kuhn (table I). However, several other observations were inconsistent. For example, intracellular survival of the relatively avirulent B. fragilis was similar to that of S. typhimurium, L. monocytogenes + H4b and the two E. coli strains (fig. 3). Also, there were no significant differences in intracellular survival between L. monocytogenes strains + H1a and −H1a and Ent. faecalis. As summarised in table IV, when all the bacterial strains in this study were considered as a group, survival within mononuclear phagocytes (fig. 3) was not consistently correlated with oral infectivity (table I).

Because listeriolysin has been considered a primary virulence factor for L. monocytogenes, some comment seems appropriate. Kuhn et al. observed that, after oral inoculation, bacterial translocation to extra-intestinal tissues occurred with a haemolytic L. monocytogenes strain, but not with a non-haemolytic mutant. Using two of the L. monocytogenes strains of the present study, others have reported that −H1a was relatively avirulent compared to +H1a by either the oral or the intraperitoneal route. After orally inoculating L. monocytogenes + H1a, −H1a, and +H4b into mice, we agree with Kathariou et al. and Tabouret et al., who concluded that listeriolysin production was not directly proportional to virulence for mice. Kuhn et al. noted that haemolysin production had no effect on uptake of listeria by mouse peritoneal macrophages. In the present study, differences in phagocytic uptake of L. monocytogenes + H1a, +H4b and −H1a were not significant (fig. 1). Kuhn et al. also reported that loss of haemolysin (transposon-induced mutation) reduced intracellular survival. In the present study, intracellular survival was not consistently correlated with haemolysin production; L. monocytogenes + H1a and −H1a produced 512 and 32 haemolytic units, respectively, yet these strains had similar intracellular survival. Furthermore, the intracellular survival of both +H1a and −H1a was significantly better than that of +H4b, an intermediate haemolysin producer. However, listeriolysin is not the only virulence factor in L. monocytogenes and summarised information on a number of genes with products that probably participate in pathogenicity.

In conclusion, the results indicated that the ability of a bacterial strain to interact with mononuclear phagocytes was not consistently associated with oral infectivity (table IV). As a caveat, it should be mentioned that proteose peptone-elicited peritoneal mononuclear cells were tested in these experiments and that either unelicited mononuclear phagocytes or mononuclear phagocytes from other tissues (e.g., spleen, liver, bone marrow) might have behaved differently. However, this study suggests that oral infectivity is not generally correlated with bacterial uptake or intracellular survival in mononuclear phagocytes.

We thank Diane Bierman and Muriel Gavin for excellent technical assistance. This work was supported by Public Health Service grant AI 23484 from the United States National Institutes of Health.
