Summary. Mice that had been treated with cyclophosphamide and ampicillin were fed with *Pseudomonas aeruginosa*. These procedures induced an endogenous septicaemia under conditions mimicking the pathophysiology of the disease in man. This model was used to compare the mortality rates in mice infected with *P. aeruginosa* isolates from various clinical sources. Mortality rates in mice given isolates from blood cultures had a broad range (0-100%), but the mean rate was significantly higher than with isolates from other infection sites. Moreover, blood isolates persisted in the intestines of mice after oral inoculation, whereas most isolates from other sources were gradually eliminated. Most *P. aeruginosa* isolates from blood culture produced significantly higher levels of exotoxin A and total proteases than isolates from other infection sites. Amongst the blood isolates, all but one of the lethal strains produced large quantities of exotoxin A or total proteases or both. Taken together, the results suggest that the ability of *P. aeruginosa* to adhere to the intestinal tract and to produce high levels of exo-enzymes may contribute to the development of fatal septicaemia.

Introduction

The mortality rate for septicaemia caused by gram-negative bacteria remains high in immunocompromised patients, despite the availability of various potent broad-spectrum antimicrobial agents. Most septicaemias in immunocompromised patients arise as a result of invasion by the endogenous microflora, particularly that of the gastro-intestinal tract.

Amongst gram-negative bacilli causing septicaemia, *Pseudomonas aeruginosa* has been associated with the highest mortality rates. We reported previously that *P. aeruginosa* also gives a high mortality rate in leukopaenic mice with endogenous bacteraemia. *P. aeruginosa* also causes severe infections in patients with burns, malignant tumours, cystic fibrosis and other diseases.

*P. aeruginosa* has several toxic cellular components, notably lipopolysaccharide, and manufacturers extracellular products such as proteases and exotoxins, that account for its virulence in these patients. Recent investigations have indicated that proteases may play an important role in the establishment and maintenance of various types of pseudomonal infections. However, the significance of these exo-enzymes in septicaemia remains unclear.

In this study, septicaemia was caused in leucopaenic mice fed with *P. aeruginosa* cultures. Unlike conventional infections models, which usually employ intraperitoneal or intravenous infection routes, this model incorporated the steps of bacterial colonisation, overgrowth and invasion, and consequently closely mimicked the pathophysiology of septicaemia in man. With this model, the mortality rates for *P. aeruginosa* strains obtained from various clinical sources were evaluated, as was the relationship between the mortality rate and the ability of the bacteria to survive in the intestinal tract and produce exotoxin A, proteases, elastase and phospholipase C in vitro.

Materials and methods

Bacteria

Thirty-five *P. aeruginosa* isolates obtained at Nagasaki University Hospital, Nagasaki, Japan were used (table I); 17 isolates were from blood, 12 from sputum, three from urine and one each from ascites, pus and other secretion. *P. aeruginosa* D4, which was isolated from the cardiac blood of a mouse with...
were examined twice daily, and deaths were recorded until day 16.

**Systemic bacteraemia, was also used. This strain consistently caused a 70-90% mortality rate in the model of endogenous septicaemia.**

Bacteria were identified with Vitek Gram-Negative Identification Cards (Vitek System Inc., Hazelwood, MO, USA). Serotypes were determined by agglutination with monoclonal antibodies (Mel-Assay; Meiji Seika Kaisha, Ltd, Tokyo, Japan).

Stock bacterial cultures were suspended in Mueller Hinton Broth (Difco) containing glycerol 30%, and stored at −80°C until required.

**Establishment of endogenous septicaemia**

A previously described model of endogenous septicaemia was used, but with some modification. Pathogen-free male ddY mice (Japan SLC Inc. Ltd, Shizuoka, Japan) weighing 20–24 g were housed in sterile plastic cages with filter hoods and given a sterile diet and distilled water ad libitum. They were given sodium ampicillin (Vicillin; Meiji) 200 mg/kg daily by intraperitoneal injection on days 1–5 to disturb the normal intestinal flora and aid colonisation by *P. aeruginosa*. Cyclophosphamide (Endoxan; Shionogi and Co., Ltd, Osaka, Japan) was given intraperitoneally at a dose of 250 mg/kg on days 6 and 9. This dose of cyclophosphamide induced leucopaenia (<1000 leucocytes/mm³) without lethality in the absence of infection.

Bacteria were grown overnight at 37°C on Trypticase Soy Agar (BBL Microbiology Systems), then suspended in sterile saline 0.45%. The density of the suspension was adjusted to 10⁷ cfu/ml by reference to a standard curve relating optical density (OD) and bacterial count. The bacterial suspension was given to the mice in their drinking water on days 2–4. The mice were examined twice daily, and deaths were recorded until day 16.

**Quantitation of faecal *P. aeruginosa* in mice**

Before the start of the study, faecal specimens from the mice were examined to confirm the absence of *P. aeruginosa*. Fresh faecal pellets were also collected from each mouse on days 6 and 10. Each sample was weighed, suspended and diluted in saline, then plated on agar containing nalidixic acid 15 mg/L and cetrimide 200 mg/L (NAC Agar; Eiken Chemical Co. Ltd, Tokyo, Japan) for selection of *P. aeruginosa*. After incubation for 24 h at 37°C, the plate counts were recorded as cfu of *P. aeruginosa*/g of faeces.

**Exo-enzyme assays**

*Exotoxin A.* Trypticase Soy Broth (BBL) dialysate (TSBD-C) was used as the growth medium for the measurement of exotoxin A. The iron content of the medium after treatment with Chelex (BioRad) was 0.1 mg/L, as determined with bathophenanthroline.

Bacteria were incubated in TSBD-C for 24 h at 32°C with vigorous shaking. After centrifugation at 3000 g, the supernates were passed through a 0.22-μm pore filter and then assayed by an enzyme-linked immuno-sorbent assay (ELISA) similar to that described previously. Briefly, microtiter plates were first coated with goat anti-exotoxin A antiserum (List Biological Laboratories Inc., CA, USA). Culture supernates, or serial dilutions of purified *P. aeruginosa* exotoxin A (List) (0.0031–12.5 mg/L in TSBD-C broth), were then added. Rabbit antiserum against *P. aeruginosa* exotoxin A (a gift from Sumitomo Chemical Co. Ltd, Tokyo, Japan) was used as a second antibody. Alkaline phosphatase-labelled goat anti-rabbit IgG antibodies (E-Y Laboratories Inc., San Mateo, CA, USA) were then added, followed by the reaction substrates detailed previously.

**Protease assays.** Total proteolytic activity was measured by the method of Woods et al. Organisms were grown for 24 h at 37°C in Brain Heart Infusion Broth (Difco) with vigorous mixing. Subsequently, 0.5-ml amounts of the culture supernates were diluted 1 in 5 in 10 mM Tris, pH 7.5, and added to 15 mg of hide powder azure (Sigma) as a substrate. The mixture was incubated at 37°C for 1 h, with vigorous shaking. Undissolved substrate was removed by centrifugation at 3000 g for 10 min. OD₅₉₅ values of the supernates were then compared with a standard curve prepared by treating the substrate for the same period with purified *P. aeruginosa* protease (Nagase Biochemicals Ltd., Kyoto, Japan) at enzyme concentrations of 0.0075–15.63 mg/L.

The assay method for elastase activity was identical to that for total protease, except that: (i) the culture supernates were diluted three-fold; (ii) 10 mg of elastin Congo red (Sigma) was used as a substrate and (iii) OD₅₉₅ was recorded. Values were compared with those of a standard curve derived with purified *P. aeruginosa* elastase (Nagase) at concentrations of 0.49–125 mg/L.

**Phospholipase C.** Organisms were grown in tryptose

Results

Mortality rates among mice with experimental endogenous septicaemia

Without an oral challenge with bacteria, no deaths occurred up to day 16 amongst mice treated with cyclophosphamide and ampicillin. By contrast, the mortality rate amongst leucopaenic mice given P. aeruginosa D4 was eight out of 10. These mice died between days 11 and 13 with systemic bacteraemia caused by the challenge strain (fig. 1).

Table II shows the mortality rates for groups of 10 mice challenged with each of 35 P. aeruginosa isolates. The mortality rates ranged widely amongst isolates from blood cultures: with isolates B1, B2, B3 and B4, no deaths were observed up to day 16, whereas isolates B13, B14, B15, B16 and B17, gave 100% mortality, with deaths occurring on days 11-14. Deaths were associated with systemic bacteraemia caused by the challenge strain. In contrast, no deaths occurred in 17 of 18 groups of mice given isolates from other infection sites besides blood. In the one group given a sputum isolate (S2) one of 10 mice died. The mean mortality rates amongst mice given isolates from blood, sputum,

* Significantly higher than for isolates from other sources (p < 0.05).

urine and other infection sites were 57, 0.8, 0 and 0%, respectively. The higher mortality rate amongst mice given blood isolates was significant (p < 0.01).

Quantification of faecal P. aeruginosa

In the mice given blood-culture isolates or strain D4, the number of P. aeruginosa cells persisted at > 10^6 cfu/g faeces on day 10 (fig. 2a). In contrast, the numbers of faecal pseudomonas tended to decrease with time when isolates from other sources were used (fig. 2b). However, exceptions to this latter pattern arose with isolates S2, S3, S6, S9 and U3. When averaged, the faecal counts for blood isolates were significantly higher than those for isolates from other sources on day 10 (5.0 x 10^7 versus 5.5 x 10^6; p < 0.01).

Quantification of in-vitro production of P. aeruginosa exo-enzymes

Differences in mean exo-enzyme levels were found between P. aeruginosa strains isolated from different infection sites (table III). On average, P. aeruginosa isolates from blood produced higher levels of exotoxin A and total proteases than strains from any other sites (p < 0.05 for both enzymes). Moreover, strains from blood and sputum produced significantly higher levels of elastase than those from other infection sites (p < 0.05).

Amongst blood-culture isolates, those causing 100% mortality tended to produce higher levels of one or more exoenzymes than those causing zero mortality (fig. 3). In particular, strains B13 and B15 produced...
high levels of exotoxin A and strain B16 produced all four exo-enzymes copiously. However, strain B14 gave 100% mortality yet produced relatively low levels of the exo-enzymes examined (fig. 3).

The serotypes of the isolates were not related to sites of isolation, mortality rates in mice, numbers of faecal bacteria or exo-enzyme levels.

Discussion

*P. aeruginosa* is frequently responsible for septicaemia in patients with malignant diseases, particularly leukaemic patients undergoing chemotherapy. Intestinal colonisation rates with *P. aeruginosa* have been reported as > 50% amongst patients with leukaemia, 20% amongst those with solid tumours, and 6–12% amongst healthy adults. Tancrede and Andremont showed that 81% of patients with bacteraemia caused by *P. aeruginosa* were intestinal carriers of the same strain. These data suggest that the *P. aeruginosa* strains causing septicaemia in patients with malignant diseases frequently originate from the intestinal flora. Routes of acquisition of *P. aeruginosa* include patient-patient or staff-to-patient contact, water, food and disinfectants, but often remain uncertain. In many cases, the patient may have been colonised before admission with small numbers of *P. aeruginosa*. Factors that promote development of endogenous septicaemia include bacterial colonisation and overgrowth in the intestine, compromised immune defences and disruption of the mucosal epithelium.

In the present study, an experimental model of endogenous septicaemia was developed. This model used oral inoculation of the bacteria to mimic the pathophysiology of septicaemia in man. In this model, *P. aeruginosa* strains isolated from blood cultures frequently caused septicaemia, whilst isolates from other sites did not do so. Moreover, blood isolates mostly persisted longer in the gut than those from other sources. These results suggest that blood isolates may carry additional virulence factors that assist colonisation, invasion, or resistance to host defences. *P. aeruginosa* exo-enzymes may contribute to corneal damage associated with ocular infections and haemorrhagic and necrotic changes in the skin and internal organs, but their contribution in septicaemia is still unclear. Therefore, we examined whether the ability of *P. aeruginosa* to produce exo-enzymes in *vitro* was related to the mortality rates amongst mice with endogenous septicaemia.

The results indicated that *P. aeruginosa* isolates from blood tended to produce higher levels of exotoxin A and total protease *in vitro* than isolates from other infection sites. These data suggested that exotoxin A and total protease may be important exo-enzymes in the development of endogenous septicaemia. Nevertheless, correlation was not total and strain B14 caused 100% mortality despite minimal production of these exo-enzymes. Similarly, amongst blood isolates causing mortality rates between 10 and 90%, some that were highly virulent formed little of the exo-enzymes *in vitro* whereas others that gave low mortality formed relatively higher levels. Further studies with mutant strains will help to understand the role of individual exo-enzymes in septicaemia.

In conclusion, some differences were demonstrated between *P. aeruginosa* strains that caused endogenous
septicaemia with high mortality rates and those caus-
ing no septicaemia, with respect to the production of
exo-enzymes and the ability of the bacteria to survive
within the intestinal tract. Exotoxin A and total
proteases may play some role in the pathogenesis of
endogenous septicaemia; but it is necessary to examine
the multifactorial nature of *P. aeruginosa* pathogenesis
since virulence did not seem to depend on any single
determinant studied.

We thank T. Usui and K. Hara for helpful suggestions, A. Saito,
