Summary. The pre-formed urease activity of three NCTC reference strains and five clinical isolates of \textit{Helicobacter pylori} was determined at room temperature (21°C) and 37°C by a viable cell count technique with a conventional urea slope test (Christensen's agar) as well as the commercial CLO-test. The urease activity of two gastroduodenal commensals, \textit{Proteus mirabilis} and \textit{Klebsiella pneumoniae}, was also tested. \textit{H. pylori} strains produced positive reactions with viable cell counts of $10^6$-$10^8$ cfu within 30 min and with counts of $10^3$-$10^6$ cfu within 2 h. For some strains, smaller numbers of organisms were needed with the CLO-test than with the conventional test, and incubation of the CLO-test strips at 37°C slightly decreased the number of organisms required for positive results. \textit{P. mirabilis} produced a positive result on urea slopes with an initial inoculum of $10^7$-$10^8$ cfu at 2 h, but no positive reaction occurred for \textit{K. pneumoniae} at 12 h, even with an initial inoculum of $10^{11}$ cfu. However, both \textit{P. mirabilis} and \textit{K. pneumoniae} gave a positive result after incubation for 24 h with initial inocula of $<10^6$ cfu and $10^3$-$10^4$ cfu respectively. Incubation at 37°C significantly reduced the inoculum size of these organisms required for a positive result after incubation for 4 h when tested with the slopes, but not with the CLO-test. These findings indicate that \textit{H. pylori} possesses much greater pre-formed urease activity than \textit{P. mirabilis} and \textit{K. pneumoniae}. False negative results for clinical detection of \textit{H. pylori} in gastroduodenal biopsies may be due to small numbers of organisms, especially after treatment with antimicrobial agents, and false positive results may arise from gastroduodenal commensals or contaminants.

Introduction

\textit{Helicobacter pylori}, formerly \textit{Campylobacter pylori}, a common pathogen of gastroduodenal diseases, possesses an unusual characteristic of rapid urea hydrolysis, forming carbon dioxide and ammonia.\textsuperscript{1} Several invasive and non-invasive methods for detecting \textit{H. pylori} infection in gastric biopsy specimens have been developed based on this characteristic. McNulty and Wise\textsuperscript{2} developed a urease test, which has been modified and evaluated by many other investigators.\textsuperscript{3-11} Later, urea breath tests with $^{13}$C- or $^{15}$C-labelled urea were established\textsuperscript{12,13} and the $^{15}$NH$_4^+$ excretion test was introduced.\textsuperscript{14} However, false results occur with these tests, and their practical use is controversial.\textsuperscript{6,15} The aim of this study was to determine the pre-formed urease activity of \textit{H. pylori}, as well as \textit{Proteus mirabilis} and \textit{Klebsiella pneumoniae}, by a viable cell count technique, and to evaluate the CLO-test by comparing it with the conventional slope urease test.

Materials and methods

Bacterial strains

The \textit{H. pylori} strains studied were three reference strains—NCTC11637, NCTC11638 and NCTC11639 (National Collection of Type Cultures, Public Health Laboratory Service, 61 Colindale Avenue, London)—and five clinical isolates—HP92181, HP92587, HP92766, HP921052 and HP93280—from gastroduodenal biopsies of dyspeptic patients. Clinical isolates of \textit{P. mirabilis} (PM617 and PM627) and \textit{K. pneumoniae} (KP620 and KP637) were also used. \textit{H. pylori} strains were subcultured on chocolate agar plates (Columbia Agar Base, Lab M, Bury, with horse blood 7%). The plates were incubated in gas jars at 37°C for 3 days immediately after flushing with CO$_2$. \textit{P. mirabilis} and \textit{K. pneumoniae} isolates were subcultured on MacConkey agar plates and incubated at 37°C for 18 h before use. Colonies were identified by Gram's stain, urease, catalase and oxidase tests and the API 20E assay (API System, S. A. La Balme Les Grottes, France).

**Urease test**

The bacterial cultures of *H. pylori*, *P. mirabilis* and *K. pneumoniae* (strains NCTC 11637, NCTC11639, HP92587, HP92766, HP921052, PM617, PM627, KP620 and KP637) were suspended in 5 ml of sterile distilled water to yield a turbidity of McFarland Standard No. 2–3. The suspensions were then diluted in 100-fold steps to 10¹⁰. One hundred μl of each dilution was placed on paired urea slopes (Christensen’s agar) and spread on chocolate agar plates or MacConkey agar plates. One pair of slopes was incubated at room temperature (21°C) and the remainder at 37°C. Slopes were examined after 30 min, 2, 4, 6, 8, 12 and 24 h and tests were recorded as positive when the yellow colour changed to pink in the area of the inoculum. Viable counts were made from the plate cultures after incubation for 5 days for *H. pylori* and 18 h for *P. mirabilis* and *K. pneumoniae*.

**Comparison of CLO-test with conventional test**

The reference strains, NCTC11638 and NCTC11639, and clinical isolates of *H. pylori*, *P. mirabilis* and *K. pneumoniae* HP92181, HP93280, PM617 and KP637, were used in the comparative tests. After suspension and dilution as above, 100 μl of each dilution were inoculated on to the agar areas of paired CLO-test strips (Delta West Ltd, Western Australia) and urea slopes. The strips were incubated at room temperature and 37°C with the slopes and read at intervals as described above.

**Results**

**Urease activity of *H. pylori*, *P. mirabilis* and *K. pneumoniae***

*H. pylori* strains produced a positive result on urea slopes with viable bacterial counts of 10⁵–10⁷ cfu after
incubation for 30 min at room temperature, but the required inoculum decreased to $10^3$–$10^6$ cfu when incubation was prolonged to 2 h (figs. 1, 3 and 5). After this time, the required inoculum remained unchanged (fig. 1). For *P. mirabilis* with an inoculum of $10^7$–$10^8$ cfu, no colour change was observed before incubation for 2 h at room temperature (fig. 2). *K. pneumoniae* possessed even less pre-formed urease and did not produce a positive result with an initial inoculum of $10^4$ cfu after 12 h at room temperature (table). However, both *P. mirabilis* and *K. pneumoniae* gave positive results at 24 h with initial inocula of $<10^4$ cfu and $10^5$–$10^6$ cfu, respectively (fig. 2 and table).

*Comparison of CLO-test with conventional test*

Smaller inocula of two of four *H. pylori* strains produced positive results with the modified CLO-test (fig. 3), but this was not so for *P. mirabilis* and *K. pneumoniae* (fig. 4 and table).

Incubation at 37°C made no difference for *H. pylori* with the conventional urease test (data not shown), but two of the four strains required a lower inoculum
with the CLO-test (fig. 5). However, for \textit{P. mirabilis} and \textit{K. pneumoniae}, incubation at 37°C significantly reduced the inoculum required for a positive result after incubation for 4 h with the conventional urease test, but not with the CLO-test (figs. 2, 4 and table).

**Discussion**

The present study showed that at least $10^8$ bacterial cells of \textit{H. pylori} were required for a positive urease reaction in the CLO-test (fig. 5). However, most strains gave a positive result with an inoculum of $< 10^6$ cfu.

The human gastric mucosa may become colonised with various bacterial species,\(^{15}\) including urease-positive bacteria other than \textit{H. pylori}.\(^{16}\) It is suggested that the urease of \textit{H. pylori} can be distinguished from that produced by \textit{Proteus} and \textit{Klebsiella} spp. by its high substrate affinity and rapid hydrolysis of urea.\(^{17}\) In this study, the pre-formed urease activity of \textit{H. pylori}, which usually acted within 2 h in the conventional urease medium, was found to be more than 100 times greater than that of \textit{P. mirabilis} and 10000 times more than that of \textit{K. pneumoniae} in terms of initial inoculum requirement.

The observations in the present study provide further evidence for the high specificity (86–100\%) and sensitivity (59–100\%) of urease tests in detecting \textit{H. pylori} infection in gastric biopsy specimens.\(^{6,4,6–11}\)
It is unlikely that \textit{P. mirabilis} and \textit{K. pneumoniae} would reach the critical concentration of $10^5$–$10^6$ cfu in gastroduodenal specimens. In patients infected with Enterobacteriaceae, the colonising concentration in gastric mucosa was only $2 \times 10^5$–$2 \times 10^6$ cfu per gastric specimen. However, Khulusi \textit{et al.} have shown that, in untreated patients with duodenal ulcer or gastritis, the density of \textit{H. pylori} infection in the gastric antrum and body is as high as $(1.3 - 6.9) \times 10^5$ cfu/g of tissue. After antimicrobial therapy, \textit{H. pylori} can be cultured from antral biopsies at concentrations of $10^6$ cfu/g of mucosa. Since gastroduodenal biopsy specimens average $c. \ 0.02$ g (authors' observation), a concentration of \textit{H. pylori} in gastric mucosa is at least $2 \times 10^6$ organisms/gastric specimen for most infected, but untreated patients, and for treated patients, the concentration can still reach $2 \times 10^5$ organisms/specimen.

The urease tests must be performed carefully and the results interpreted cautiously. Firstly, although most \textit{H. pylori} strains produce positive results at 2 h, an incubation time of $> 4$ h, and up to 24 h, may be required for a few strains (fig. 5). To avoid overgrowth of urease-positive gastric commensals or contaminants, bacteriostatic or bactericidal agents should be included in the reaction media if prolonged incubation is expected. This principle has been applied to the CLO-test. Sensitivity and specificity may also be improved by accelerating the action of pre-formed urease of \textit{H. pylori}, e.g., by changing the concentration of the substrate or the indicator or both, or by changing the indicator. Incubation at $37^\circ$C slightly increases the sensitivity for some strains (fig. 5), but it will also increase the possibility of the false positive results due to gastric commensals or contaminants that grow rapidly at $37^\circ$C (figs. 2, 4, and table). False negative results may occur in some situations. For example, the number of organisms in gastroduodenal biopsies will be reduced significantly (even if not fully eradicated) by antimicrobial agents or \textit{H. pylori}-suppressing drugs. Finally, since the distribution of \textit{H. pylori} in gastric mucosa is patchy, false negative results may occur when the biopsy specimen contains small numbers of organisms.

The urease test is simple, easy, rapid and cheap. It has high specificity and sensitivity for detecting \textit{H. pylori} in the gastric mucosa, and is suitable for primary diagnosis in patients undergoing endoscopy. However, other methods that are not based on urease activity may be needed for some patients, especially those who have been treated already with antimicrobial agents.

We thank Mr L. English of the Department of Clinical Microbiology, St James's Hospital, Dublin, for his helpful technical advice and useful discussion.
