Differences in the immune responses of mice and sheep to an aromatic-dependent mutant of Salmonella typhimurium

F. R. BRENNAN*, J. J. OLIVER and G. D. BAIRD

Moredun Research Institute, Gilmerton Road, Edinburgh

Summary. A live mutant aroA Salmonella serotype Typhimurium ovine strain (S25/1) could be cultured from tissues of mice for up to 90 days after oral infection. Following vaccination, high levels of Salmonella-specific serum IgM, IgG and IgA were produced in addition to high levels of specific intestinal IgA. Moreover, there was also evidence of Salmonella-specific cell-mediated immunity in vaccinated mice in the form of strong delayed-type hypersensitivity and the production of interferon-gamma (IFN-γ) by spleen cells stimulated with Salmonella antigen. The aroA strain was also recovered from the mesenteric lymph nodes and most tissues examined from sheep vaccinated by the oral route. Salmonella-specific IgM was detected in the serum; however, specific IgG responses were very low and there was an absence of specific copro-antibody. Although strong Salmonella-specific lymphocyte proliferative responses were detected, they did not result in the production of IFN-γ and flow cytometric analysis revealed that the proliferating cells were predominantly B lymphocytes. Despite the absence of strong vaccine-specific immune responses in vaccinated sheep compared with those seen in mice, both mice and sheep were protected against challenge with virulent wild-type strain S25/1.

Introduction

Salmonellosis is a worldwide infectious disease of man and animals. As well as being a serious public health hazard, salmonellosis is of economic importance to the livestock industry, causing enteric infection, abortion and death in ruminant animals. This situation has been made worse by intensive husbandry practices and the stressful conditions associated with transit and shipping.

Salmonella serotype Typhimurium is one of the commonest causes of salmonellosis in man and animals in the UK,1,2 hence control of this particular serotype is a priority. Although Salmonella spp. are susceptible to antibiotics, this form of treatment either as a prophylactic or therapeutic measure is expensive and poses an undesirable risk of selection of antibiotic-resistant mutants. Thus, vaccination would offer the best means of control. Live vaccines have been shown to provide better protection against challenge with virulent Salmonella strains than killed vaccines.3,4 Such live vaccines also have the advantage that they provide longer-lasting immunity, can be administered via the oral route and do not cause the unpleasant side-effects often associated with killed vaccines given by injection.8 Moreover, live vaccines do not require an adjuvant to elicit strong cell-mediated immunity (CMI).9

AroA mutants of Salmonella have emerged as candidate live vaccine strains against salmonellosis. They are characterised by a non-reverting block in the common aromatic biosynthetic pathway as a result of a transposon-generated deletion within the aroA gene.10 Such mutant strains have been shown to be avirulent and effective as vaccines in mice,10,11 poultry,12 calves5,15 and sheep.7,15,16 The aim of this study was to examine the immunogenicity of an aroA mutant strain of Typhimurium and its ability to protect both mice and sheep from wild-type challenge. Experiments were designed to compare and characterise the immune responses to the vaccine strain in mice and sheep and to give an insight into the mechanisms that might mediate protection against virulent challenge.

Materials and methods

Media

Bacterial strains were cultured routinely in Luria-Bertani (LB) Broth or on LB Agar (Difco). The complete media used for the isolation of salmonellae were Xylose Lactose Deoxycholate (XLD) agar (CM467B; Oxoid), Nutrient Broth No. 2 (code CM67; Oxoid) and Selenite Broth Base (code CM395; Oxoid) containing sodium biselenite (code L121; Oxoid) 4 g/L.
**Bacterial strains**

The aroA mutant Typhimurium strain used in this investigation was derived from a virulent ovine field strain (S25/1) by transposon mutagenesis by the method of Hoiseth and Stocker. The aroA and wild-type strains were cultured in LB broth in flasks with shaking at 37°C for 18 h. After centrifugation at 7500 g for 10 min, the pellet was washed three times in phosphate-buffered saline (PBS) and resuspended in PBS. The viable count (cfu/ml) was determined by the agar plate count technique. The killed preparation of the vaccine strain was produced by heating the homogenate of sheep intestine was measured by an enzyme-linked immunosorbent assay (ELISA) and the specific delayed-type hypersensitivity (DTH) was measured. In a second experiment, five mice received

**Clinical parameters**

The demeanour of all the mice and sheep following vaccination and challenge was examined closely. Food intake was assessed every 24 h. The rectal temperature of the sheep was measured daily and faecal samples taken on alternate days, from which the percentage dry weight was determined. The percentage packed cell volume of sheep blood samples, taken on days 2–12 after vaccination with S25/1aroA and on each day after challenge with wild-type strain S25/1, were determined to measure the extent of haemoconcentration.

**Blood collection**

Blood was collected from halothane-anaesthetised mice after cutting the hepatic vein. Blood was removed from the jugular veins of sheep and sera were stored at −20°C.

**Recovery of S25/1aroA from specimens from mice and sheep**

Faecal pellets, liver, spleen and all Peyer’s patches (free of intestinal wall) from each mouse were homogenised separately in 10 ml of PBS in a “Stomacher 80” lab blender (Seward Medical, London) and 1 ml of homogenate was plated on to XLD agar. After incubation of the plates at 37°C for 18 h, viable counts were determined and expressed as the mean log10 cfu/g of the organ or faeces. Homogenates of tissue samples (1 g in 10 ml of PBS) from each sheep were also made and viable counts done as described above. The organs examined included heart, lung, bronchial lymph node, liver, hepatic lymph node, spleen, kidney, mesenteric lymph node, abomasum, ileum, caecum and colon. When bacteria could not be isolated after direct plating on to XLD agar, 1 ml of homogenate was first enriched in 10 ml of selenite broth and then plated on to XLD agar. Viable counts were expressed as log10 cfu/g of tissue for each sheep.

**Collection of intestinal IgA**

Mice were dosed orally every 15 min for 1 h with 0.5 ml of 48.5 mm polyethylene glycol (mol. wt 3350; Sigma); 20 min after the last dose, the mice were culled and the intestines and caeca were washed out twice with 5 ml of ice-cold 50 mm EDTA containing soybean trypsin inhibitor (Sigma) 0.1 mg/ml. Samples were adjusted to 6 ml with ice-cold PBS and centrifuged at 2500 g for 10 min. Three ml of supernate were centrifuged at 69000 g at 4°C for 20 min after which 30 μl of 0.2 M phenylmethyl-sulphonylfluoride (PMSF) in ethanol 95% v/v and 30 μl of sodium azide 2% w/v were added to 2 ml of clarified supernate. Fetal calf serum (FCS; Sigma) was added at 3% and the samples were stored at −70°C. Faecal samples from sheep were homogenised in ice-cold EDTA-soyabean trypsin inhibitor; homogenates were centri-
fuged at 25000 g for 10 min and sodium azide was added to the supernate to a final concentration of 0·01% w/v. FCS (100 µl/ml) was added to the samples, which were then stored at −70°C.

Extraction of lipopolysaccharide (LPS)

The hot phenol-water extraction procedure29 was used for extracting LPS from a live 18-h culture of S25/laroA. Highly purified LPS was obtained by preparative ultracentrifugation as described by Lindberg and Holme.30

Immunological parameters

S25/laroA-specific antibody titres in the sera of individual mice or sheep were measured by an ELISA as described previously.25 Purified LPS from S25/laroA, at a concentration of 1 µg/ml, was used to coat the ELISA plates (M129B; Dynatech). Anti-mouse IgM, IgG and IgA conjugated to alkaline phosphatase were obtained from Sigma. Horseradish peroxidase-labelled anti-sheep immunoglobulin conjugates were produced at MRI. The optical density (OD) of post-vaccination serum was obtained by subtracting the OD of normal mouse serum.

DTH reactions

DTH skin reactions to intradermal injection of 50 µl of a heat-killed preparation of S25/laroA (containing 2 × 10⁶ cfu/ml) were measured. Changes in flank thickness were assessed by measurement with dial-gauge calipers (Kroeplin, Germany) before, and 24 and 48 h after injection of antigen.

Lymphocyte transformation tests (LTTs)

PBMC were obtained by passing heparinised whole blood over Lymphoprep (Nycomed, Oslo, Norway).32 Murine spleen cells were obtained by injecting 10 ml of Hanks's Balanced Salts Solution (HBSS) containing heparin 1% under the splenic capsule. Both PBMC and spleen cells were washed twice in HBSS by centrifugation at 400 g for 5 min, counted and resuspended in Iscove’s Modification of Dulbecco’s Medium (IMDM; Flow, Irvine) containing FCS (100 µl/ml) supplemented with FCS (Sigma) 2% and sodium azide 0·5% w/v, counted and 1 × 10⁶ cells were resuspended in the appropriate monoclonal antibody (MAb). The MAbs used were mouse anti-sheep CD4, CD8, T-cell receptor gamma-delta (r-δ) and immunoglobulin light chain. Anti-Border Disease virus MAb was used as a negative control. After 1 h on ice, the cells were washed twice in EBSS at 400 g, resuspended in 50 µl of a 1 in 25 dilution of fluorescein-labelled rabbit anti-mouse IgG conjugate (Dako Ltd) and incubated on ice in the dark for 1 h. After two more washes in EBSS, the cells were fixed in 400 µl of paraformaldehyde 1% in EBSS and stored at 4°C in the dark until examined on a FACSCAN (Becton-Dickinson) with Lysis 1 software.

Statistical analysis

Student’s unpaired t test was used to calculate significant differences (p < 0·05) between control and experimental groups.

Results

Clinical responses after vaccination with S25/laroA

No clinical symptoms developed in any of the mice or sheep following vaccination.

The distribution of S25/laroA in vivo after oral inoculation

After oral inoculation of mice, salmonellae were isolated from all tissue and faecal samples examined from day 6 until day 54 when Peyer’s patches were free from infection (fig. 1). The organism was recovered

Fig. 2. Specific serum antibody in (a) mice and (b) sheep after oral vaccination with strain S25/\textit{laroA}. The sera were tested in an ELISA for \textit{Salmonella}-specific IgM (-----) and IgG (---). Mouse serum was diluted 1 in 200 for both IgM and IgG and sheep serum was diluted 1 in 200 and 1 in 40 for IgM and IgG, respectively. Each point represents the mean OD$_{405}$ of five mice or the mean OD$_{492}$ of five sheep. Mean OD values are expressed as a percentage where 100\% represents OD 1.8.

from the liver until day 78 and was still present in the spleen and being excreted in faeces at the termination of the experiment on day 90.

In sheep, the mesenteric lymph nodes contained substantial numbers of the vaccine strain and varying levels of colonisation were present in the majority of other tissues taken from each sheep at both times tested (table I).

BLN, bronchial lymph node; HLN, hepatic lymph node; MLN, mesenteric lymph node; +, organism detected only after enrichment.

* Sheep were inoculated orally with three doses of $10^{11}$ cfu of strain S25/\textit{laroA} on days 0, 2 and 4 and three sheep were culled on days 6 and 12.

Serum antibody responses in mice and sheep after oral vaccination with S25/\textit{laroA}

Titres of serum IgM and IgG antibody to LPS of the vaccine strain were determined by ELISA and the results for both mice and sheep are shown in fig. 2. In mice, IgM began to appear between days 18 and 21 and rose to high titres by day 28 before falling, although antibodies were still detectable on day 90.
IgG appeared on day 21, reached high levels by day 28 and remained high until termination of the experiment.

In sheep, IgM appeared on day 5 and rose steadily until day 12 when titres started to fall. Titres of IgG were much lower than for IgM and appeared on days 8–12, remaining relatively constant throughout the subsequent course of the studies.

**Intestinal antibody responses in mice and sheep after oral vaccination with S25/laroA**

Titres of intestinal (gut) IgA in mice against LPS of the vaccine strain were determined by ELISA and are shown in fig. 3, where they are compared with the serum IgA titres. Intestinal IgA antibody appeared on days 14–18 with serum IgA appearing slightly later. The antibody profiles of intestinal and serum IgA were very similar; titres of both rose together and reached high levels on days 36 when they started to fall. High titres of intestinal IgA were sustained for longer than serum IgA; however, both were still detectable on day 90.

In sheep, copro-antibody was not detected in any of the five sheep at any time, even after challenge with wild-type strain S25/1.

**Salmonella-specific lymphocyte proliferative responses of mice and sheep after vaccination with S25/laroA**

The proliferative responses of spleen cells to Salmonella antigen are shown in fig. 5a for 12 mice vaccinated 35 days previously with $2 \times 10^9$ cfu of S25/laroA and for 12 unvaccinated mice. Although all the vaccinated mice produced strong proliferative responses following antigen stimulation which were significantly different from those of the unvaccinated mice, six of the unvaccinated mice showed high responses. These responses in unvaccinated mice were not due to the presence of intestinal flora which cross-reacted with Typhimurium, as germ-free BALB/c mice responded in the same way (results not shown). A more likely explanation for these responses is that high levels of LPS in the antigen preparation caused polyclonal stimulation of B cells in certain spleen cell cultures.

All five sheep showed responses to strain S25/laroA at all times after vaccination which were significantly greater than before (day 0) vaccination (fig. 5b).

**Production of IFN-γ in response to Salmonella antigen in vitro by spleen cells or PBMC from aroA-vaccinated animals**

Cells from both mice and sheep were stimulated with antigen 35 days after vaccination. The titres of supernates taken 96 h after antigen stimulation are shown in table II. Titres of supernates taken 24 and 48 h after stimulation were very similar and hence are not shown. All 12 vaccinated mice produced IFN-γ whereas none of the unvaccinated mice did so. None of the vaccinated or unvaccinated sheep produced IFN-γ following stimulation with Salmonella antigen (results not shown).

**Specific DTH responses in mice and sheep after oral vaccination with S25/laroA**

Specific increases were detected as early as day 9 after vaccination in mice, remained constant until 6 weeks and then increased steadily until termination of the experiment (fig. 4). In some unvaccinated mice, no increase in the footpad thickness was detected and in others the response was negligible.

In sheep, large non-specific increases in skin-fold thickness were recorded in all sheep irrespective of whether they had been vaccinated, making the results impossible to interpret. As an alternative, the in-vitro responsiveness of the PBMC to Salmonella antigen was examined in an LTT.
were not due to T-lymphocyte proliferation. Therefore, the cell-surface phenotype of the responding cells were determined by flow cytometry before and 35 days after vaccination with the S25/1aroA strain. Before vaccination the proliferative responses in the LTT were low (fig. 5b), and of the responding cells (blast cells), 68% expressed the immunoglobulin light chain, i.e., were B cells (fig. 6b). After vaccination, there was an increase in the percentage of the total cells that were B cells (from 21 to 50%) (fig. 6a) of which c. 90% were blast cells. There was no increase in either the total number of CD4+, CD8+ or T-cell-receptor γδ+ cells, or in the number of blast cells expressing these molecules following vaccination. Thus, it appears that

Fig. 4. Specific DTH responses in mice inoculated orally with \( 5 \times 10^7 \) cfu of strain S25/1aroA. The Salmonella-specific increases in footpad thickness were determined at the stated times after infection. Each point represents the mean increases in mm of five mice. Vertical bars indicate SD. Unvaccinated mice produced increases of 0–0.4 mm, highlighting the specificity of the test.

Fig. 5. Specific lymphocyte proliferative responses of mice and sheep after vaccination with strain S25/1aroA. A, mice 1–12 were vaccinated orally with strain S25/1aroA while mice 13–24 were unvaccinated. The Salmonella antigen-induced LTTs were determined on day 35 after vaccination and the incorporation into thymidine was counted as cpm. B, Five sheep were vaccinated orally with four doses of strain S25/1aroA and the PBMC were cultured with Salmonella antigen before and at various times after vaccination. Mean cpm values for each time-point are shown with standard deviations (vertical bars); *p < 0.01.
Fig. 6. Phenotype of cells responding to Salmonella antigen in vitro. PBMC from five sheep were stimulated with Salmonella antigen before and 51 days after vaccination with four doses of (5-9) x 10^7 cfu of strain S25/aroA. The mean percentage of both (a) total cells and (b) blast cells that were CD4+(■), CD8+ (□), T-cell receptor (TcR) τ-δ+ (■) and Ig light chain (LC)+ (□) were compared at these two time-points.

The responses of PBMC to Salmonella antigen were due to specific B-cell proliferation in the absence of T-cell responses.

Challenge of aroA-vaccinated mice and sheep with wild-type strain S25/1

All vaccinated mice were protected from challenge with the virulent strain and showed no clinical signs of infection. However, all the unvaccinated mice developed severe clinical signs and succumbed to infection between days 5 and 8, when the organism was recovered from the spleens, livers and Peyer’s patches in high numbers (10^5-10^6 cfu/g of tissue).

The mean rectal temperatures of both the vaccinated and unvaccinated groups of sheep are shown in fig. 7. After 48 h, pyrexia was observed in all the vaccinated sheep (0.7-2.4°C), but they all looked well, retained their appetites and no haemoconcentration was observed. By 72 h the temperatures had dropped, although pre-vaccination temperatures were not reached until 14 days after challenge. Only one sheep developed diarrhoea (from days 7 to 12) but it remained otherwise clinically well throughout, and all four remaining sheep produced faecal pellets throughout the course of the challenge. The sheep were culled on day 18 after challenge when most of the tissues tested were free of the challenge strain (table III). The aroA vaccine strain could still be recovered from the organs of three of the sheep at this time.

In contrast to the mild clinical responses seen in vaccinated sheep, unvaccinated sheep developed a lethal infection. After 24 h there was an increase (2.3-3.0°C) in rectal temperatures of all the sheep and loss of appetite was observed until termination of the

* Spleen cells from 12 unvaccinated mice and 12 mice vaccinated 30 days previously with 5 x 10^7 cfu of strain S25/aroA were cultured with decreasing doubling dilutions (from 10^7 cfu/well) of Salmonella antigen for 4 days when the titres of IFN-γ in the supernates were determined (see Materials and methods).

Fig. 7. Rectal temperature responses in vaccinated (---) and unvaccinated (——) sheep after challenge with wild-type strain S25/1. Five sheep vaccinated orally 40 days previously with four doses of (5-9) x 10^7 cfu of strain S25/aroA, and five unvaccinated sheep were challenged orally with 8 x 10^7 cfu of wild-type strain S25/1 and the mean rectal temperatures for the two groups were recorded on each day after challenge; *p < 0.01, †p < 0.05.
term persistence of the vaccine strain produced high titres of Salmonella-specific IgM, IgG (J. J. Oliver, unpublished observations). Earlier IgA, although titres in serum generally appeared 1-2 days later. This suggests that there may be absorption of IgA produced in the gut into the bloodstream of the mucosa, or simultaneous priming of IgA-producing B cells in the intestine and in the lymph nodes. Such association of serum and gut IgA has not been reported in man following oral vaccination with a live Typhi vaccine (Ty21a).25

The strong vaccine-specific humoral responses in mice were in contrast to the much reduced responses in sheep. Salmonella-specific serum IgM was detected in relatively high amounts; however, levels of specific serum IgG were low and specific copro-antibody was absent. These findings are in accordance with those of Lascelles et al. who were unable to detect IgA-producing B cells in the sheep intestine after repeated oral vaccination with aroA Typhimurium.26 They found that primary oral immunisation gave rise to mainly IgM-producing cells. Others have been unable to detect serum antibody after oral vaccination with aroA Typhimurium.13,16

Mice produced strong vaccine-specific DTH responses that were still increasing 90 days after infection. DTH testing did not prove effective in demonstrating T-cell immunity in sheep, as all sheep produced strong responses whether or not they had been vaccinated, making the results impossible to interpret. Oral vaccination of sheep with aroA Typhimurium has been shown to be ineffective in eliciting Salmonella-specific DTH responses to the LPS and flagella of the vaccine strain.7,15,16 However, the lack of responses to LPS were not surprising as it is a T-cell-independent B-cell mitogen.

To try and detect T-cell responses to the vaccine in sheep, and to further demonstrate T-cell responses in vaccinated mice, the proliferative responses of ovine PBMC and murine spleen cells to Salmonella antigen were examined. Both mice and sheep cells produced strong Salmonella-specific responses after vaccination, but only murine cells produced IFN-γ in response to antigen stimulation. The lack of IFN-γ production by PBMC from vaccinated sheep suggested that it was B cells that were responding, or that a population of T cells that does not produce IFN-γ, such as Th2 cells were responding. Furthermore, phenotype analysis also showed that the responding cells were predominantly B cells and there was no increase in the percentage of T cells after vaccination. This would account for the lack of IFN-γ in PBMC culture supernates from these sheep, predominance of IgM in the serum and lack of IgG and IgA, as these latter responses are T-cell-dependent.

Despite the quite different responses to S25/1aroA in mice and sheep after oral vaccination, both species were completely protected against a lethal dose of the wild-type strain and only mild clinical responses were seen in vaccinated sheep. Unvaccinated sheep developed a lethal infection and the organism were recovered in high numbers from the gut and systemic tissues compared with the low numbers recovered from vaccinated sheep.

BLN, bronchial lymph node; HLN, hepatic lymph node; MLN, mesenteric lymph node.

* Five sheep vaccinated 40 days previously with four doses of 10^{11} cfu of strain S25/1aroA, and five unvaccinated sheep were challenged orally with 8 x 10^9 cfu of wild-type strain S25/1. The unvaccinated sheep were culled on day 18. The vaccinated sheep were culled on day 18.

Experiment. The mean rectal temperatures of the unvaccinated sheep were significantly higher than those of the vaccinated group on all days tested. There was a significant increase (p < 0.05) in the percentage packed cell volume of the blood, rising from a mean pre-infection level of 36.6 to 44.1%. Sheep were culled on day 3 when two of the sheep had developed diarrhoea and all five sheep were clearly in distress. The mesenteric lymph nodes and the intestines of all the sheep contained high numbers of the challenge organism but only in sheep no. 3 were high numbers recovered from other tissues (table III). This may be a result of the early culling of these animals.

Discussion

In this study, mice infected orally with 1 x 10^8 cfu of strain S25/1aroA showed no clinical signs and did not succumb to infection. BALB/c mice have been shown to tolerate doses of 5 x 10^8 cfu of strain S25/1aroA (J. J. Oliver, unpublished observations). Earlier studies estimated the oral LD50 of the wild-type strain to be 2 x 10^8 cfu; hence there is a difference of at least 10^6 cfu in the minimum oral LD50 of the aroA and wild-type strains of S25/1 in BALB/c mice. The aroA strain colonised the reticulo-endothelial system of both mice and sheep after oral infection and there was long-term persistence of the vaccine strain in vivo, as it was recovered from the mice on day 90 and from the sheep on day 58.

Oral vaccination of mice with a single dose of aroA produced high titres of Salmonella-specific IgM, IgG and IgA in the serum, and IgA in the intestine. Titres of serum IgA antibody reflected those of intestinal IgA, although titres in serum generally appeared 1-2
In conclusion, the results show that strain S25/\(laraO\) is an effective live vaccine in mice and sheep against experimental salmonellosis, although the immune responses mediating this protection may be quite different in the two species.
