Summary. Two Salmonella typhimurium isolates were studied, one as a representative from a series of neonatal meningitis cases treated at an Istanbul teaching hospital, the other from a gastro-enteritis case seen at a different Istanbul hospital. Both isolates were resistant to extended-spectrum cephalosporins, as well as penicillins, aminoglycosides and chloramphenicol. Cephalosporin resistance depended on production of PER-1 β-lactamase, which is an extended-spectrum class A enzyme that is only distantly related to TEM and SHV enzymes, and which was previously known only from Pseudomonas aeruginosa isolates. The PER-1 gene was carried by an 81-MDa plasmid, which also determined resistance to aminoglycosides and chloramphenicol. Although it was not self-transmissible to Escherichia coli, this element did transfer if mobilised with plasmid pUZ8. The two S. typhimurium isolates gave indistinguishable DNA restriction patterns and, in addition to their 81-MDa plasmid, also contained 52- and 2·8-MDa plasmids, the last of these encoded TEM-1 enzyme. The two isolates were identical in serotype, antibiogram and plasmid-profile but nevertheless differed in phage type, and, therefore, represented distinct strains. The emergence of cefotaxime and ceftriaxone resistance in salmonellae is disturbing, since these agents are preferred therapy for neonatal meningitis caused by members of the genus.

Introduction

Salmonella infections are frequent throughout the developing world and are a major health concern in Istanbul, Turkey.1 Besides causing self-limiting gastro-enteritis, salmonellae are also responsible for invasive diseases, including bacteraemia and neonatal meningitis. Ampicillin and chloramphenicol have long been the first-line treatments for invasive salmonella infections, but increasing resistance means these drugs can no longer be recommended in many developing countries, including Turkey. Alternative therapies include quinolones and two cephalosporins, cefotaxime and ceftriaxone. Quinolones are preferred for most salmonella infections, but the cephalosporins may be better in neonatal meningitis, because quinolones penetrate the CSF poorly and can adversely affect cartilage development.2 Unfortunately, however, cephalosporin-resistant salmonellae have been reported from North Africa and Malaysia.3, 5 These isolates owed their resistance to extended-spectrum mutants of TEM or SHV β-lactamases. We now describe cephalosporin-resistant S. typhimurium isolates from Istanbul. These produced PER-1 β-lactamase, an extended-spectrum type that is only distantly related to the TEM and SHV enzymes, and which previously was known only from Pseudomonas aeruginosa isolates.6

Materials and methods

Patients and isolates

Four neonates, who were born over a 4-month period in the same delivery room of an Istanbul teaching hospital, each developed S. typhimurium meningitis 1–17 days after birth, and were admitted to the neonatal intensive care unit of the hospital (table I). No source of the infections was identified, although carriage by staff was suspected. The isolates were
resistant to chloramphenicol, ampicillin, cefotaxime and ceftriaxone, but were susceptible to ciprofloxacin (see Results). Three of the neonates were treated with ciprofloxacin (10 mg/kg 12-hourly), but only one survived. The serotypes, biotypes, antibiotic resistance patterns and plasmid profiles of the isolates from the four patients were identical and one, designated “D”, was chosen for study. The other cephalosporin-resistant S. typhimurium isolate studied here, designated “B”, was from a patient who presented with gastro-enteritis at a hospital on the other side of Istanbul. (The Bosphorus is a sea channel that connects the Sea of Marmara to the Black Sea, thereby separating Europe and Asia and dividing Istanbul into two halves). No epidemiological link was identified between this patient and those seen in the neonatal unit.

Isolates B and D were identified with API 20E strips (bioMérieux, La Balme les Grottes, France) and were serotyped by slide agglutination tests with O-, H- and H2-specific antisera. Serotyping results were reconfirmed by the Salmonella Section of the National Microbiology Institute of Turkey, and by the Laboratory of Enteric Pathogens, Central Public Health Laboratory, Colindale, London. The latter establishment also undertook phage typing.

Escherichia coli K-12 J53-1 pro, Nal7 was used as a recipient in transfer experiments. Plasmid pUZ8,6 encoding resistance to kanamycin, tetracycline and mercurials, was used as mobilising plasmid. E. coli NCTC 50192,6 that contains plasmids of 98, 42, 239 and 46 MDa, was used as a source of markers for plasmid electrophoresis. Reference producers of TEM-1, TEM-2 and SHV-1 β-lactamases were from our strain collection, and E. coli JM109 with plasmid pPZ1,6 encoding PER-1 enzyme, was generously provided by P. Nordmann, Paris.

Antibiotics and susceptibility tests

Antibiotics were from suppliers as follows: chloramphenicol, ciprofloxacin and sulphamethoxazole from Sigma; ampicillin sodium and clavulinate lithium from SmithKline Beecham, Brentford, Middlesex; ceftriaxone from Roche, Welwyn Garden City, Hertfordshire; piperacillin sodium and tazobactam from Lederle, Gosport, Hampshire; ceftazidime from Glaxo, Greenford, Middlesex; amikacin and aztreonam from Bristol-Myers Squibb, Syracuse, NY, USA; cefotaxime from Roussel, Uxbridge, Middlesex; cefoxitin and imipenem from Merck Sharp and Dohme, Hoddesdon, Hertfordshire; and meropenem from Zeneca, Macclesfield, Cheshire.

MICs were determined on IsoSensitest agar (Unipath) with inocula of 104–105 cfu/spot, delivered by a semi-automated multipoint inoculator (Mast, Merseyside). Results were evaluated after incubation for 18 h at 37°C, and the MICs were read as the lowest concentrations to prevent growth completely.

Plasmid analysis and detection of β-lactamase genes

The rapid procedure of Kado and Liu16 was used to detect plasmids and to estimate their sizes. Briefly, plasmids were extracted from overnight cultures grown in nutrient broth and were electrophoresed at 12 V/cm for 1–2 h in agarose 0.9% in TBE buffer, then stained with ethidium bromide. Size estimation was by comparison to the migration of the plasmids of strain NCTC 50192. To detect the β-lactamase genes, the plasmid DNA was transferred to Hybond-N nylon membranes (Amersham International, Amersham, Buckinghamshire), by a positive-pressure blotter (Posiblot, Stratagene, Cambridge), and then hybridised with appropriate probes. The PER-1 gene probe was the PCR product of blaPER amplified, as described below, from a P. aeruginosa producer and labelled with digoxigenin by means of a random labelling kit (Dig DNA Labeling and Detection Kit, Boehringer, Lewes, E. Sussex). The blaTEM probe was as described previously.11 Hybridisations were performed at 68°C under high-stringency conditions.12 Plasmids were isolated for transformation experiments by a mini-prep method.13

Transconjugation and transformation

For conjugation experiments, equal volumes of exponentially-growing nutrient-broth cultures of the S. typhimurium donors and the E. coli K-12 J53-1 recipient were mixed and spread on nutrient-agar plates. After overnight incubation at 37°C, the growth was harvested into saline 0.9% and spread on nutrient agar containing nalidixic acid 100 mg/L plus either ceftazidime 32 mg/L or ampicillin 64 mg/L, to select transconjugants.

*Day post-diagnosis of meningitis.
†Patient from whom isolate D was obtained.
In some experiments, plasmid pUZ8 was first introduced into the salmonellae. This was achieved by plate-mating as above, but with *E. coli* J53-1 (pUZ8) as the donor and *S. typhimurium* strains B and D as recipients. Transconjugant selection was on nutrient agar containing tetracycline 64 mg/L plus ceftazidime 32 mg/L. The pUZ8-containing salmonellae thereby obtained were then mated with *E. coli* K-12 J53-1, and transconjugants were selected, as above, on agar containing ceftazidime plus nalidixic acid.

*E. coli* K-12 J53-1 cells were prepared as competent recipients for transformation by a standard method. Briefly, the bacteria from an exponentially growing broth culture were washed and resuspended in ice-cold 50 mM CaCl₂, then held at 0°C for 2 h. Plasmids, prepared as above from the salmonellae, were then added and the cells were heat-shocked at 42°C for 2 min. Transformants were selected on nutrient agar containing cefazidime, 32 mg/L.

**Extraction and iso-electric focusing of β-lactamasess**

Overnight cultures from nutrient-agar plates or slopes were harvested into 0.01 M phosphate buffer, pH 7.0, and β-lactamases were released by sonication. Debris was removed by centrifugation at 12000 g for 15 min. The supernatants were resuspended in ice-cold 50 mM CaCl₂, then held at 0°C for 2 h. Plasmid DNA was purified by precipitation with ethanol, redissolved in distilled water and then dialysed overnight against 0.1 M Tris-HCl, pH 8.0.

β-Lactamase activity was measured in 0.1 M Tris-HCl, pH 8.0, and p-lactamases were released by sonication. Iso-electric focusing was performed on gels (230 mm x 100 mm x 1 mm) prepared essentially as described by Matthew et al., but supplemented with sucrose 10% w/v as an osmotic buffer. After focusing, the β-lactamases were located by overlaying the gels with 1 mM nitrocefin in 0.1 M phosphate buffer, pH 7.0, and β-lactamases were released by sonication.

Transconjugants were designated *B* and *D* gave identical API profiles (no. 6704752) and gave agglutination reactions with the following salmonella-specific antisera: O₁₅₅.₅,₁₂, H₁, and H₄₋₂. These are typical profiles for *S. typhimurium*. Despite their differing origins, isolates B and D had identical antibiograms, being resistant to penicillins, cephalosporins, aztreonam, aminoglycosides, chloramphenicol and sulphonamides, although susceptible to imipenem, meropenem and tetracycline (table II). Cefazidime resistance was reversed by clavulanate 4 mg/L, but not by tazobactam 4 mg/L. Iso-electric focusing revealed that both isolates produced β-lactamases that focused at pI values of 5.3 and 5.4 (fig. 1), although it was not immediately apparent whether these enzymes were distinct, or were satellites of a single type. Both isolates had plasmids of c. 81, 52 and 2.8 MDa (fig. 2). The 81-MDa plasmid hybridised with the PER-1 gene probe and the 2.8-MDa plasmid hybridised with the TEM gene probe.

Despite all their similarities the two isolates gave distinct phage reactions: isolate B was of phage type 29 and isolate D was of type 193.

**Resistance transfer and characterisation of the transconjugants and transformants**

Strains B and D readily transferred ampicillin resistance to *E. coli* K-12 J53-1 in plate-mating experiments, and representative ampicillin-selected transconjugants were designated *E. coli* K-12 J53-1 (B amp) and J53-1 (D amp), respectively. These transconjugants did not acquire resistance to extended-spectrum cephalosporins, chloramphenicol or amino-glycosides (table II). Iso-electric focusing revealed that they have acquired the pl 5.4 β-lactamase, but not the pl 5.3 type. Plasmid electrophoresis detected the 52- and 2.8-MDa plasmids, but not the 81-MDa plasmid.

Cephalosporin resistance was conjugatively transferred from the salmonellae only if plasmid pUZ8 was first introduced into them. The transconjugants thereby obtained, designated *E. coli* K-12 J53-1 (B trg) and J53-1 (D trg), had qualitatively similar antibiograms to the donor salmonellae, except that they were less resistant to cefotaxime, cefazidime and cefixime/tazobactam and remained fully susceptible to sulphonamides. These transconjugants expressed both the pl 5.3 and 5.4 β-lactamases and acquired plasmid pUZ8, with the same estimated mol. wts as those present in the donors. Tetracycline resistance, coded by pUZ8, was not retained in the.

*Plasmid pPZ1 carried the PER-1 β-lactamase-encoding gene cloned from P. aeruginosa RNL-1.

Fig. 1. Iso-electric focusing patterns of β-lactamases from the salmonella isolates, their transconjugants and their transformants. Track 1, TEM-2 enzyme; 2, TEM-1; 3, isolate B (TEM-1 + PER-1); 4, B amp' (TEM-1); 5, B trfm (PER-1); 6, B trcj (TEM-1 + PER-1); 7, TEM-1; 8, isolate D (TEM-1 + PER-1); 9, D amp' (TEM-1); 10, D trfm (PER-1); 11, D trcj (TEM-1 + PER-1); 12, TEM-1; 13, TEM-2; 14, PER-1. Note that the TEM-1 band is barely visible in the extracts of the two isolates; it was apparent when large amounts of extract were applied to the gel but, under these circumstances, the rapidly-diffusing reaction from the PER-1 enzyme precluded successful photography.

Resistance to cephalosporins was also transferred to E. coli K-12 J53-1 by transformation with total plasmid DNA extracted from strains B and D. The transformants thereby obtained were designated E. coli K-12 J53-1 (B trfm) and J53-1 (D trfm). They were similarly resistant as E. coli K-12 J53-1 (B trcj) and J53-1 (D trcj), except to piperacillin (MIC 16 mg/L for the transformants, 512 mg/L for the transconjugants) (table II). The transformants acquired only the PI-5.3 enzyme, not the PI-5.4 type, and only the 81-MDa plasmid, not the 52- and 2.8-MDa plasmids. The 81-MDa plasmid was confirmed to contain sequences that hybridised with the PER-1 gene probe.

Fig. 2. Plasmids of transconjugants and transformants of isolate B. Track 1, B amp' (2.8- and 52-MDa plasmids); 2, B trcj (2.8, 52 and 81 MDa); 3, B trfm (81 MDa); 4, pUZ8 (40 MDa); 5, NCTC 50192. Similar results were obtained for isolate D, its transconjugants and transformants.

PCR amplification and sequencing of blaER-1

Primers A and D were used to amplify the PER gene from the E. coli transformants. In each case, a PCR product of c. 926 bp was detected by agarose gel electrophoresis and ethidium bromide staining, and was confirmed to hybridise with the PER gene probe.
The sequence of this product was determined with the aid of the primers PER A, PER B and PER C, and proved identical to the \( \text{bla}_{\text{PER-1}} \) sequence reported by Nordmann and Naas\(^{16} \) except that guanine at position 386 was replaced by adenine. This change altered a codon from GCG to GCA but would not change the amino acid (alanine) encoded.

**Discussion**

This study demonstrated that PER-1 \( \beta \)-lactamase, albeit with one silent mutation to its encoding gene, caused resistance to third-generation cephalosporins in two isolates of *S. typhimurium* obtained in Istanbul, Turkey. One of these organisms was a representative from a series of neonatal meningitis cases seen at a teaching hospital on the Asian side of the Bosphorus; the other was from a gastro-enteritis patient who presented at the hospital on the European side of the Bosphorus. In each isolate the PER-1 enzyme was coded by an 81-MDa plasmid, that also determined resistance in enterobacteria rather than *Pseudomonas aeruginosa*. Production of the enzyme has not, as yet, been demonstrated in any isolate that cannot be traced back to Turkey. The original producer strain, *P. aeruginosa* RNL-1, was obtained in Paris but was from a patient transferred from Ankara (P. Nordmann, personal communication) and 14 further *P. aeruginosa* isolates with the enzyme were detected amongst ceftazidime-resistant *P. aeruginosa* strains collected at Hacettepe University Hospital, Ankara during 1991–1993.\(^{15} \) The finding of PER-1 \( \beta \)-lactamase in enterobacteria is surprising since the original enzyme from strain RNL-1 had a promoter that failed to give expression in enterobacteria;\(^{16} \) nevertheless the codon usage of \( \text{bla}_{\text{PER-1}} \) suggests an origin outside pseudomonas.\(^{16} \)

Production of PER-1 enzyme was plasmid-mediated in the present isolates, being coded by an 81-MDa element. The enzyme gene was found on two different large (> 100 MDa) plasmids among the *P. aeruginosa* isolates from Hacettepe Hospital\(^{19} \) and, contrary to what was initially thought,\(^{9} \) is coded by a plasmid in strain RNL-1 (Danel and Livermore, unpublished observations). Detection of \( \text{bla}_{\text{PER-1}} \) on several different elements suggests that the gene may be transposon-borne, as are the genes encoding many other class A \( \beta \)-lactamases.

When it was not accompanied by TEM-1 enzyme, PER-1 \( \beta \)-lactamase gave marked cephalosporin resistance in *E. coli* but only slightly reduced susceptibility to piperacillin. Cephalosporin resistance was substantially reversed by clavulanate, although not by tazobactam. Similar resistance patterns arise when PER-1 enzyme is produced by *P. aeruginosa*.\(^{15} \) By contrast, the extended-spectrum TEM and SHV \( \beta \)-lactamases, give substantial piperacillin resistance in enterobacteria and can be inhibited by both tazobactam and clavulanate.

The emergence of extended-spectrum \( \beta \)-lactamases in salmonellae merits concern. These organisms are frequent causes of neonatal meningitis in many developing countries, and are often already resistant to ampicillin and chloramphenicol. Cefotaxime and ceftriaxone are rational alternative treatments, although other cephalosporins are compromised by poor CSF penetration and inadequate killing of intracellular bacteria.\(^{17} \) However, cefotaxime and ceftriaxone will be lost as therapy if extended-spectrum \( \beta \)-lactamases, such as PER-1, become prevalent in the genus. The physician then will be forced to use quinolones, which have poor CSF penetration and potential side-effects on cartilage development. Of the four neonates considered here, three received ciprofloxacin but only one survived. Meropenem may be an option in the future, being stable to extended-spectrum enzymes including PER-1, and, unlike imipenem, suitable for use in meningitis. As yet, however, this drug has not been validated or licensed for neonatal use.

We are grateful to Brigid Duke and Ismail Sisman for excellent technical assistance and to the Laboratory of Enteric Pathogens, PHLS Central Public Health Laboratory, London, and Mikrobioloji AD, Capa Tip Fakultesi, Istanbul, for typing the isolates.
