Summary. An association between human papillomavirus (HPV) and cervical neoplasia has been widely reported and HPV DNA is commonly detected in cervical carcinoma tissues. However, estimates of the prevalence of HPV infection differs among various detection methods. Seventy cases of cervical carcinoma were screened for HPV 16 infection by Southern blot hybridisation (SBH) and nested polymerase chain reaction (PCR). According to SBH, the prevalences of HPV 16 DNA in stage I (n = 40) and stage II (n = 30) cervical carcinomas were 52.5 and 63.3 %, respectively, and the overall prevalence was 57.1 % (40 of 70). By nested PCR, the prevalences of HPV 16 infection in stage I and II cervical carcinomas were 87.5 and 93.3 %, respectively, and the overall prevalence was 90.3 %. The prevalence of HPV DNA detected by nested PCR was significantly greater than that detected by SBH. The combined concordance of positive and negative results between SBH and nested PCR was 61.4 %. The discrepancy resulted mainly from 25 cases (35.7 %) that were positive by PCR but negative by SBH. A small copy number of HPV DNA in these 25 cases was documented by a semi-quantitative PCR method. The nested PCR was more sensitive than SBH and detected cases with low amounts of HPV DNA. The detection of HPV infection varied between these two prevailing detection methods and this should be kept in mind in assessing various epidemiological data concerning HPV infection.

Introduction

The association of human papillomavirus (HPV) infection and cervical neoplasia has been widely reported. More than 60 genotypes of HPV have been identified and > 22 genotypes are related to genital infection. Among them, HPV types 6 and 11 are more commonly seen in benign gynaecological lesions such as condylomata acuminata, whereas HPV types 16 and 18 are more commonly seen in malignancies of the lower genital tract, especially cervical carcinomas. The prevalences of HPV 16 and 18 DNA in cervical carcinoma tissues greatly exceed those in normal cervical tissues.

The prevalence of HPV infection varies between reports. The recorded prevalence rates of HPV 16 or 18 DNA in cervical carcinoma tissues by hybridisation methods in the UK, Germany, the USA and Japan range from 18 % to 92 %. The great variation in prevalence may result from geographic or racial differences. However, other factors such as test design and detection methods may also be responsible for the discrepancy. Although Southern blot hybridisation (SBH) is generally accepted as the ultimate standard method, it is expensive and laborious and a large amount of sample is required for analysis. Moreover, the sensitivity and specificity can be increased by means of a two-step PCR with nested primers. Nested PCR has been applied to detect hepatitis C virus (HCV), human immunodeficiency virus (HIV), herpes simplex virus (HSV) and HPV. Exploring the variation in prevalence detected by SBH and PCR is important in assessing epidemiological data of HPV infection. In the present work, HPV 16 DNA, the most prevalent virus in cervical carcinoma tissues, was screened by both SBH and PCR methods and the underlying cause of the discrepant screening results
between these two methods was sought by application of a semi-quantitative PCR analysis.

**Materials and methods**

**Subjects and specimens**

Seventy cases of histologically proven cervical carcinoma were studied. The clinical staging of cervical cancer followed the system of the International Federation of Gynecology and Obstetrics (FIGO). There were 40 stage I (57.1%) and 30 stage II (42.9%) cases. The mean ages of cases with stage I and stage II disease were 46.6 and 51.2 years, respectively. The difference in ages between these two groups of patients was not significant (t = 1.71, p = 0.092). The carcinoma tissues were collected from the surgical specimens immediately after radical hysterectomy and stored in liquid nitrogen until use. The genomic DNA of carcinoma tissues was extracted by a phenol-chloroform-ethanol method and the concentrations of genomic DNA were determined by spectrophotometry.20

**Southern blot hybridisation**

Southern blot hybridisation was done as described previously.8 Briefly, genomic DNA (10 μg) was digested with restriction endonucleases such as BamHI, HindIII and PstI, then subjected to agarose gel electrophoresis and subsequently blotted on to nitrocellulose membranes. The HPV probes were labelled with [γ-32P]-dCTP. Prehybridisation, hybridisation and washing were performed under highly stringent conditions. Hybridisation was detected by autoradiography. The sensitivity of SBH was c. 1 pg of standard HPV DNA.

**PCR**

Cellular genomic DNA (500 ng, each case) and purified HPV DNA (100 pg, positive control) were used as target DNA. Each sample was amplified in a reaction mixture (10 μl) containing: PCR buffer—50 μM KCl, 10 mM Tris-HCl, pH 8.3, 1.5 mM MgCl2 and gelatin 0.01%; primers mix, each 0.2 μM, (outer primer pairs in the first-step PCR and inner primer pairs in the second-step PCR); dNTP (deoxy-nucleoside triphosphate, mix: dATP, dTTP, dCTP, dGTP; Sigma, each 50 μM); and Taq DNA polymerase (Cetus, USA), 2 units. Salmon sperm DNA (500 ng) was used as the negative control and reaction mixture without target genomic DNA was used as the blank. Amplification was performed with an automated thermal cycler (Perkin-Elmer Cetus, USA) with denaturing conditions of 95°C for 2 min, followed by repeated cycles of 94°C, 55°C and 72°C for 1 min each (35 cycles in total), and a final extension at 72°C for 10 min. After the first-step PCR, a portion (10 μl) of the reaction mixture was used as the source of target DNA in the second-step PCR for further amplification. The PCR reaction was prepared in a hood restricted to this purpose. There was overnight treatment of laminar flow and ultraviolet irradiation in the hood between each run of the PCR. The sequences of nested outer and inner primers used in the two steps of the PCR are shown in table I.

After each run of the PCR, the reaction mixtures were tested for positive signals by gel electrophoresis and dot-blot hybridisation. For gel electrophoresis, 15 μl of reaction mixture was separated by electrophoresis on an agarose 1.6% gel stained with ethidium bromide. Positive bands of corresponding size were recorded (fig. 1). For verification by dot-blot hybridisation, 15 μl of reaction mixtures were dot-blotted onto a nylon membrane. Prehybridisation was followed by hybridisation with non-isotopic, digoxigenin-labelled HPV oligonucleotide probes (10 ng/ml) derived also from PCR incorporating digoxigenin-dUTP.21 After stringent washing and development with a digoxigenin-anti-digoxigenin-alkaline phosphatase system, according to the manufacturer's instructions (Boehringer Mannheim, Germany), positive signals were recorded for comparison. Only those samples that gave positive bands in electrophoresis and dot signals were interpreted as positive for HPV infection. The sensitivity of nested PCR was tested with serial dilutions of standard HPV DNA. As little as 10^-6 pg of standard HPV DNA was detectable by this method.

**Semi-quantitative PCR**

To prepare a competitive DNA fragment for semi-quantitative PCR, the originally amplified native HPV 16 DNA fragment (694 bp; nucleotides 7836–625) was

Fig. 1. Agarose gel electrophoresis of amplified HPV 16 DNA fragments from genomic DNA of cervical carcinoma tissues following nested PCR. Upper row (first-step PCR): lane 1, size marker, Phi-X174/HaeIII (1 pg); 2-4, positive (694 bp) and negative controls and blank, respectively; 5-17, samples. Lower row (second-step PCR): lane 1, size marker, Phi-X174/HaeIII (1 pg); 2-4, positive (552 bp) and negative controls and blank, respectively; 5-17, samples.

Fig. 2. Relative intensity of amplified HPV DNA bands on electrophoresis following semi-quantitative PCR. Lane 1, size marker, Phi-X174/HaeIII; 2-4, 0.1, 0.01 and 0.001 pg, respectively, of native HPV DNA in addition to 0.1 pg of modified HPV 16 DNA in the reaction mixtures; 5-7, 0.1, 0.01 and 0.001 pg, respectively, of native HPV DNA in addition to 0.01 pg of modified HPV 16 DNA; 8-10, 0.1, 0.01 and 0.001 pg, respectively, of native HPV DNA in addition to 0.001 pg of modified HPV 16 DNA. The iso-dense bands of the amplified native (694 bp) and the modified competitive (494 bp) HPV DNA appeared when the relative amounts of these two DNA templates in the samples were similar, e.g., lanes 2 and 6.

Results

Prevalence by Southern blot hybridisation and nested PCR

The prevalences of HPV 16 DNA in cervical carcinoma tissues by SBH in stage I and stage II patients were 63.3% (19 of 30) and 52.5% (21 of 40), respectively. The overall prevalence rate was 57.1% (40 of 70) (Table 1). Conversely, the prevalences of HPV 16 DNA in cervical carcinoma tissues by nested PCR in stage I and stage II patients were 87.5% (35 of 40) and 93.3% (28 of 30), respectively. The overall prevalence rate was 90.0% (63 of 70). The difference in

prevalence between stage I and stage II patients was not significant either by SBH ($\chi^2 = 0.439, p = 0.508$) or by nested PCR ($\chi^2 = 0.162, p = 0.687$). However, the overall prevalence rate by nested PCR (90.0%) was much greater than that by SBH (57.1%) ($\chi^2 = 17.78, p < 0.001$).

**Comparison of prevalences detected by Southern blot hybridisation and nested PCR**

Comparisons between SBH and nested PCR for detecting HPV 16 DNA in cervical carcinoma tissues are shown in Table III. In total, 38 (54.3%) patients had concordant positive and five (7.1%) cases had concordant negative results by SBH and PCR methods. The combined concordance of positive and negative results between these two methods was 61.4% (43 of 70). The discrepancy resulted mainly from 25 (35.7%) cases, whose samples were positive by nested PCR but negative by SBH. The amounts of HPV 16 DNA determined by the semi-quantitative PCR in the samples from these 25 cases were in the range $10^{-2}$-$10^{-5}$ pg. On the other hand, samples from two (2.9%) further cases were positive for HPV 16 DNA by SBH but negative by nested PCR. The concordance of SBH and PCR results in those with stage II cervical carcinomas (70%) was greater than in those with stage I disease (55%) but the difference was not significant ($\chi^2 = 1.506, p = 0.217$).

As previously reported, the prevalence of HPV infection was not related to the clinical stage of the cervical cancers. The difference in prevalence between stage I and stage II patients, either by SBH or PCR, was not significant in this study. However, the prevalence of HPV infection detected by nested PCR was much greater than that by SBH.

PCR is generally many times more sensitive than Southern blot or other hybridisation methods. Melchers and colleagues reported that the prevalence of HPV DNA in cervical scrapes detected by PCR (70%) was much larger than that by SBH or modified filter in situ hybridisation (FISH) (46%). Moreover, the prevalence of HPV infection according to PCR in those with abnormal Pap smear (67%) exceeded that by the ViraPap method in Burmer’s series (47%). A similar result was reported by Bauer et al. In contrast, Nuovo and colleagues reported a lower detection rate of HPV in cervical lesions that lack koilocyte atypia with PCR than with SBH. The lower detection rate of HPV with PCR might have been related to the relatively high proportion of "novel" HPV types in such lesions. In the present work, the prevalence of HPV 16 DNA in cervical carcinoma tissues detected by nested PCR was 90%, much larger than that by SBH (57.1%) and also larger than the prevalence by one-step PCR method in cervical carcinoma specimens from women in central China (72%). Generally, the sensitivity of two-step PCR is greater than that of one-step PCR and the specificity is also increased by applying nested primers. Moreover, hybridisation of the PCR product with radioactively or non-radioactively labelled oligonucleotide probes increased the sensitivity of HPV detection by 100-fold.

The combined concordance of positive and negative results of HPV DNA between dot-blot hybridisation and PCR was 69% in Morris’s series, whereas the concordance between SBH and PCR was > 80% in Guerrero’s series. In this work, the concordance between SBH and nested PCR was 61.4%. Most discrepancies resulted from the 25 (35.7%) cases that gave positive PCR but negative SBH results. Similar results (27.5% of cancer biopsies were positive by PCR but negative by SBH) have been reported by Kristiansen and colleagues. These findings might be explained by the relatively small copy number of HPV DNA in carcinoma tissues from these cases. In semi-quantitative PCR analysis, the amounts of HPV 16 DNA in the samples of these 25 cases with discrepant PCR and SBH results were in the range $10^{-2}$-$10^{-5}$ pg, which was less than the detection limit (1 pg) of SBH. On the other hand, results in two cases (2.9%) were positive for HPV DNA by SBH but negative by nested PCR. This discrepancy might result from non-specific binding by SBH to other HPV DNA or the presence of novel HPV types incapable of amplification by PCR with type-specific primers.

In conclusion, the variation in prevalence of HPV DNA in cervical carcinoma tissues detected by SBH and nested PCR.
and nested PCR was evident and the discrepancy resulted mainly from cases having positive PCR but negative SBH results. Based on semi-quantitative PCR analysis, we believe that more cases with relatively small copy numbers of HPV DNA could be detected by nested PCR than by SBH. The influence of different screening methods on the prevalence rate of HPV infection is important; this factor should be kept in mind in assessing epidemiological data concerning HPV infection.

We thank Dr H. zur Hausen for providing HPV-positive plasmids and the National Science Council of Taiwan for financial support.
