Helicobacter trogontum is a micro-aerophilic urease-positive bacterium that has recently been isolated from the intestinal mucosa of rats. The purpose of this investigation was to study the ultrastructural details of this micro-organism in both pure culture and in the gastrointestinal tract of germ-free mice infected with H. trogontum. The micro-organism was a fusiform to slightly spiral gram-negative cell, 4–6 μm long and 0.6–0.7 μm wide, with four to seven bipolar sheathed flagella. The cytoplasm presented several irregular and also globular granules. On each side of the polar regions of the cells, there was a highly electron-dense band, the ‘polar membrane’. Coccoidal forms were seen in old cultures. H. trogontum showed several ultrastructural characteristics of the Helicobacter genus and much resemblance to H. rappini and H. bilis. H. trogontum mainly colonised the large bowel of the gnotobiotic mice where it could be seen in the lumen and also inside the enterocytes. Vacuolation of the ileal epithelial cells, loss of microvilli and pronounced desquamation of the enterocytes of the caecum were observed in the bowel colonised by the bacterium. These observations raise the possibility that H. trogontum could cause some harm to the host at least in particular circumstances such as when it colonises the gastrointestinal tract of a germ-free host.

Introduction

Helicobacter pylori is a curved, gram-negative bacterium that colonises the gastric mucosa of man [1]. Currently, H. pylori is implicated as an agent of chronic gastritis and peptic ulcer disease and also as an important factor in the pathogenesis of gastric adenocarcinoma and MALT lymphoma [2–5]. Since the discovery of this micro-organism the genus Helicobacter has been expanding rapidly and, because of the interest in understanding the association between H. pylori and gastroduodenal disease, other members of the genus have received increasing attention in comparative studies. For rodents, seven Helicobacter species have been identified: H. muridarum [6], H. hepaticus [7], H. bilis [8], Flexispira rappini (that has been reclassified as a member of the genus Helicobacter [9]), H. cholecystus [10] and, more recently, H. trogontum [11] and H. rodentium [12]. There is also a report suggesting that the human pathogen H. cinaedi is a natural inhabitant of the intestinal tract of hamsters [13].

Unlike H. pylori and some other gastric helicobacters, the species observed in rodents seem not to cause disease when they are in their natural habitats and they are considered part of the normal microbiota of the intestine, although some of them can be related to disease when found at other sites in the host [7, 8, 14, 15].

Morphological studies of new Helicobacter spp. reveal novel and also common structures of the genus, providing clues about what features are likely to be involved in the colonisation of the gastrointestinal mucosa and in the causation of disease [16].

H. trogontum has been described recently and there is little information about the ultrastructure of this organism [11]. Therefore, the purpose of this investigation was to study the ultrastructural details of H. trogontum in pure culture and in the gastrointestinal tract of gnotobiotic mice.
tract of germ-free mice infected with the micro-organism.

Materials and methods

In-vitro study

The type strain of *H. trogontum* (ATCC 700114) was grown on sheep blood agar 10% for 1–7 days at 37°C in micro-aerophilic conditions.

Negative staining. Colonies from a 48-h culture were transferred to a 10 mM Tris-HCl buffer, pH 7.4, to obtain a heavy suspension of bacteria. One drop of the mixture was applied to a formvar-coated 300-mesh copper grid for 1 min. Excess fluid was removed and replaced with a drop of phosphotungstic acid 1% w/v, pH 6.5, for 20–30 s and examined with a Zeiss E.M. 10.

Ultra-thin sections. After incubation for 1, 2, 3, 5 and 7 days, the colonies were harvested from plates, separately transferred to saline 0.85% to obtain a heavy mixture and centrifuged at low speed. The pellets obtained were fixed in glutaraldehyde 2.5% v/v buffered with 0.1 M sodium cacodylate, pH 7.2, for 1 h at room temperature and gently washed three times (10 min each) in sodium cacodylate 0.1%. The pellets were then carefully included in agar 2%, post-fixed in osmium tetroxide 1% w/v buffered with 0.1 M sodium cacodylate, pH 7.2, for 40 min at room temperature, washed with 0.1 M sodium cacodylate and dehydrated in a graded alcohol series for Epon embedding. Ultra-thin sections were collected on 300-mesh copper grids, stained with uranyl acetate 5% w/v for 10 min and lead citrate for 5 min and examined with a Zeiss E.M. 10.

In-vivo study

Three 4-week-old germ-free mice (NIH, Taconic, Germantown, USA) were inoculated orally with the type strain of *H. trogontum* (ATCC 700114) and maintained in micro-isolator cages under sterile conditions for 3 weeks, after which they were killed by spinal dislocation. Fragments from each region of the gastric and intestinal mucosa were immediately fixed in glutaraldehyde 2.5% v/v buffered with 0.1 M sodium cacodylate, pH 7.2, for 3 h at room temperature, and placed in three changes of 0.1 M sodium cacodylate, pH 7.2, for 10 min each. The fragments that were considered to be *H. trogontum*-positive by the two microbiological tests were processed as described above for ultra-thin sections of *H. trogontum* culture.

Fragments from each region of the gastric and of the intestinal mucosa of non-infected germ-free mice were also employed for ultrastructural evaluation.

Results

In-vitro study

Light microscopic examination of carbol fuchsin-stained smears from 24–48-h cultures of *H. trogontum* showed fusiform to slightly curved cells with granules that appeared larger than the width of the organism. These granules showed metachromasia when stained with toluidine blue. After incubation for 3 days the granules were found less frequently and there were some coccoidal cells. Colonies of 5–7-day-old cultures showed almost exclusively coccoidal forms.

Electron microscopic examination showed that the morphology of *H. trogontum* resembled that of *H. rappini* and *H. bilis*. In negatively stained preparations, *H. trogontum* was seen as a fusiform to a slightly curved cell, 4–6 μm long and 0.6–0.7 μm wide, with four to seven sheathed flagella at both ends and periplasmic fibres that were coiled around the length of the cell giving a criss-cross appearance to the bacterium (Fig. 1).

Ultra-thin sections of the micro-organism showed the typical ultrastructure of gram-negative organisms with an outer membrane and a plasma membrane separated by a periplasmic space. The organism was slightly tapered towards the ends of the cell and the sites of the insertion of flagella were flattened (Fig. 2A). On each side of the polar regions of the cells, there was a highly electron-dense band, the ‘polar membrane’, that was closely adherent to the plasma membrane (Fig. 2B). The cytoplasm was granular with a large number of ribosomes, several irregular and also spherical granules (Fig. 2B and C). These granules were seen more frequently in 24–48-h cultures.

Ultrastructural evaluation. Fragments from each region of the gastric and intestinal mucosa were immediately fixed in glutaraldehyde 2.5% v/v buffered with 0.1 M sodium cacodylate, pH 7.2, for 3 h at room temperature, and placed in three changes of 0.1 M sodium cacodylate, pH 7.2, for 10 min each. The fragments that were considered to be *H. trogontum*-positive by the two microbiological tests were processed as described above for ultra-thin sections of *H. trogontum* culture.

Microbiological evaluation. Two mucosal fragments from each region of the stomach and of the intestine were employed for the urease test and for carbol fuchsin-stained smears. One specimen was smeared on to a glass slide, heat-fixed, stained with carbol fuchsin and examined under oil immersion lens for the presence of fusiform to slightly spiral bacteria. For the urease test, the specimen was inserted into Christensen's urea agar. The test was considered positive when the colour of the medium changed from amber to pink within 12 h.
mice. Although the urease test was positive with samples from the duodenum and jejenum of the animals, it was not possible to detect either bacteria or any apparent cellular alteration in these regions of the bowel by electron microscopy.

In contrast, although bacteria were only rarely present in the ileum, a large number of vacuoles were observed in the epithelial cells (Fig. 3A and B). In the caecum, numerous bacteria were seen both in the lumen (Fig. 4A) and inside the enterocytes where they were observed isolated or mostly in clusters in the cytoplasm (Fig. 4B). The clusters consisted of a variable number of bacteria and were frequently localised near the nucleus of the cells (Figs. 4B and 5A). Also, pronounced desquamation and loss of microvilli were observed in this region in infected animals (Fig. 5A, B and C). Structures of different sizes and densities were consistently seen in the cytoplasm of the epithelial cells of the ileum, caecum and colon (Figs. 3A, 4B and 5). Bacteria were infrequently observed in the colon, where less evident alterations were found (Fig. 5D).

Discussion

As the Helicobacter genus has been defined primarily on genotypic rather than on phenotypic grounds, it comprises species that are ultrastructurally very diverse [16]. Some of the characteristics that are shared by almost all members of the genus are the typical cell wall structure of gram-negative bacteria, the cytoplasm with intracellular granules, the presence of polar sheathed flagella, the ‘polar membrane’ in the terminal region of the organism that seems to be related to energy production for movement, and alteration to the cocoidal form in old cultures [16]. In addition to these features, H. trogontum has an arrangement of periplasmic fibres and bipolar tufts of sheathed flagella resembling those of H. muridarum, H. rappini and H. bilis. With the exception of H. muridarum, which has a helically coiled body, the other two are also straight to slightly curved fusiform bacteria.

It has been postulated that the spiral shape and the active flagella enable the Helicobacter species to move easily in a viscous environment such as the mucus of the gastrointestinal tract [17]. It is possible that the periplasmic fibres coiled around the length of the fusiform helicobacters may also be related to motility, as the ridges formed by them could increase torque in the mucus or the fibres themselves could be contractile and produce rotation of the cell [6, 16].

H. trogontum presented prominent intracellular granules of different shapes, as has been observed in other species of this genus [16, 18]. The nature of these granules differs in different prokaryotic organisms, but they almost always function in the storage of energy or serve as a reservoir of structural building blocks [19]. The positive metachromatic staining of the
Fig. 2. Ultra-thin sections of *H. trogontum* culture. A, detail of a tip of the bacterium showing the cell wall and the flattened end of the cell (bar = 0.1 μm); B, the ‘polar membrane’ (arrow) and granules (bar = 0.1 μm); C, two cells longitudinally sectioned showing the serrated appearance of the micro-organism contour given by the periplasmic fibres and the granular cytoplasm with irregular and spherical granules (bar = 0.5 μm); D, coccoidal form of a 4-day-old *H. trogontum* culture (bar = 0.25 μm).
**H. trogontum** granules suggests that they contain polyphosphate.

Although species that resemble **H. trogontum**, such as **H. muridarum**, **H. rappini** and **H. bilis**, are considered natural inhabitants of the intestine of rodents, they seem to have the ability to elicit disease when found at other anatomical sites of the host or in other host species. **H. muridarum** has occasionally been observed in the gastric mucosa of mice and rats where its presence is associated with gastritis [15, 16, 20]. **H. bilis** colonises, besides the lower intestine, the bile and liver of aged inbred mice and is associated with multifocal chronic hepatitis [8]. **H. rappini** is a normal inhabitant of the intestinal mucosa of mice, but has also been isolated from aborted sheep fetuses and stools of humans with chronic diarrhoea [14]. Another rodent species that is also associated with disease is **H. hepaticus** [7]. Although not sharing many morphological characteristics with **H. trogontum**, **H. hepaticus** is most closely related to it on the basis of 16S tRNA sequence analysis [11].

Investigations are required, to determine whether **H. trogontum**, like these other rodents species, is potentially virulent and, under certain circumstances, has the ability to colonise other anatomical regions of the gastrointestinal tract besides the colon in its natural host.

In gnotobiotic mice inoculated with **H. trogontum**, the bacterium could be detected in the small and large bowel. Another study with a larger number of animals is in progress in our laboratory to elucidate the pattern of **H. trogontum** colonisation and the histopathological changes it can induce in the gastrointestinal tract of gnotobiotic mice.

Several clusters of bacteria were seen inside the enterocytes, mainly in the caecum of the gnotobiotic animals. Tissue invasion by helicobacters has seldom been reported [21, 22]. **H. pylori** has been identified within the lamina propria of gastric epithelium, but mucosal invasion is rare [23]. Endocytosed bacteria in gastric mucosa were well documented in one ultrastructural study of **H. mustelae** in the ferret [24]. In a study by Phillips and Lee [25] on the pattern of colonisation of a spiral bacterium (lately classified as **H. muridarum**) in the intestine of conventional and gnotobiotic rodents, intracellular organisms were consistently seen only in the intestinal tissues of the latter. The authors have hypothesised that this phenomenon

**Fig. 3.** Ultra-thin section of the ileum of a **H. trogontum**-positive mouse. A, pronounced vacuolation and structures with different densities (arrow) in the cytoplasm of the epithelial cell (bar = 2.0 μm); B, higher magnification of vacuoles (bar = 1.0 μm).
Fig. 4. Electron micrography of the caecum of an infected mouse showing: A, *H. trogostum* within the lumen of a gland (bar = 1.0 μm); B, bacteria in clusters and free (arrowheads) in the cytoplasm of the epithelial cells (bar = 2.0 μm).
Fig. 5. Ultra-thin section of the caecum (A, B, C) and the colon (D) of a mouse infected with *H. trogontum* showing: A, a bacterial cluster occupying the entire cytoplasm and dislodging the nucleus to the top of the cell, note the loss of microvilli of the neighbouring cell (bar = 5.0 μm); B, degenerated cell without microvilli, presenting a pyknotic nucleus and structures with different shapes and densities (bar = 5.0 μm); C, damaged cell with several bacteria free (arrowhead) in cellular debris and structures with different densities (arrow) (bar = 2.0 μm); D, transverse section of a bacterium on the surface of a colon enterocyte (bar = 1.0 μm).
may occur either as a consequence of bacterial overgrowth leading to increased tissue invasion or as a consequence of the reduced defence mechanisms of gnotobiotic hosts. This could also be an explanation for the intracellular bacteria observed in the present study. However, the alterations in epithelial cells of the intestine, as well as the tissue invasion by the bacteria, observed in the present study seemed to be more pronounced than those reported by Phillips and Lee [25].

Intense vacuolation of the epithelial cells of the ileum were observed. Vacuolation has also been observed in cells of the antral mucosa of *H. pylori*-positive patients [26, 27]. As a subset of *H. pylori* strains expresses a cytotoxin that induces cellular vacuolation in a number of different epithelial cell lines in vitro [28], it is important to investigate whether *H. trogontum* has the ability to produce a similar virulence factor. Other degenerative changes that have been observed in the gastric mucosa colonised by *H. pylori* [27], such as loss of microvilli and increased epithelial cell desquamation, were also observed in the large bowel of *H. trogontum*-positive mice.

These observations suggest that *H. trogontum*, although probably part of the indigenous microbiota of the colonic mucosa of rats, may have the ability to cause harm to the host under certain conditions, as demonstrated in the present study, where *H. trogontum* colonised the gastrointestinal tract of a germ-free host.
