BACTERIAL PATHOGENICITY

Some immunological properties of lipopolysaccharide from *Acinetobacter baumannii*

*Acinetobacter baumannii*, mainly biotype 9, is an important nosocomial opportunist pathogen in Chile and other countries. The biological basis of its virulence and prevalence is still unknown. As lipopolysaccharide (LPS) is often associated with virulence, some biological properties of purified LPS from seven nosocomial isolates, comprising four isolates of *A. baumannii* biotype 9, two isolates of biotype 8 and one isolate of biotype 1, were investigated. LPS was extracted and purified from each isolate by the hot phenol-water method, and its ability to elicit a mitogenic response and to induce the synthesis of *α* tumour necrosis factor (TNF-α) in mouse spleen cells was determined. Activity was evaluated in vivo by determining the splenic index in comparison with LPS from *Salmonella Typhimurium*. All seven LPS samples were mitogenic on the basis of cellular proliferation experiments and six induced synthesis of TNF-α. Similar results were obtained in in-vivo experiments in which LPS induced spleen cell growth, as shown by determination of the splenic index. These results suggest that the LPS of *A. baumannii* might contribute to the pathogenic properties of this species.

Introduction

*Acinetobacter baumannii*, mainly biotype 9, has become an important opportunistic pathogen in Chilean hospitals [1–3]. This species is also being reported with increasing frequency worldwide as an aetiologic agent of hospital-acquired infections [4–6]. Its importance as a nosocomial pathogen is reflected in its increasing frequency of isolation and its multiresistance to antimicrobial agents [1, 3, 6, 7]. Studies conducted with clinical isolates of *Acinetobacter* inoculated in to mice have shown that its virulence is similar to that of *Escherichia coli*, *Serratia marcescens* or *Pseudomonas aeruginosa*. However, the biological basis of the virulence of *A. baumannii* is still unknown [8]. One possibility is that lipopolysaccharide (LPS) might play a role in virulence, as has been shown for other bacterial species [8–11].

LPS from gram-negative bacteria contains a mixture of molecules with side chains of varying lengths [12–14]. This molecular heterogeneity results in the classical ‘ladder-like’ patterns observed following SDS-PAGE and staining with silver nitrate [12–14]. LPS has several biological activities that can be measured either in vitro or in vivo [15, 16]. Thus, blastogenicity can be evaluated by determining growth of spleen cells in vivo [17]. Results of these studies show a good correlation with in-vitro tests such as those for mitogenicity induced by lipid A with B cells or induction of cytokine synthesis, i.e., tumour necrosis factor α (TNF-α) and interleukin-1α (IL-1α), in mouse spleen cells [17].

LPS containing long O-specific sugar chains (S-type LPS) has been associated with virulence in other bacteria [15, 16], and previous studies in this laboratory have shown that nosocomial isolates of *A. baumannii* from Chile also produce an S-type LPS [18]. The aim of this work was to evaluate, both in vivo and in vitro, the effect of challenging cells with purified LPS from *A. baumannii*. The splenic index, the lymphoproliferative response and the TNF-α synthesis induced by the LPS were used as indicators of the biological activity.

Materials and methods

Mice

Female BALB/c mice aged 6–8 weeks were used to investigate the immunological properties of LPS. These mice were housed and handled according to the animal research guidelines of the Universidad de Concepción.

Bacterial strains and growth conditions

Four isolates of *A. baumannii* biotype 9, two isolates of biotype 8 and one isolate of biotype 1 were included in the study. These isolates were from the hospitals of three cities located in distant areas of Chile, and were identified and biotyped according to Bouvet and Grimont [19, 20]. Inocula were prepared by growing the isolates in Trypticase-Soy Broth (Life Technologies) at 37°C, with rotatory shaking at 150 rpm. The isolates were maintained in glycerol 20% v/v at -20°C.

LPS extraction

LPS was extracted from 10-L cultures as described by Westphal and Jann [21], followed by treatment with lysozyme (Sigma) 25 mg/L, DNAase I (Sigma) 25 mg/L and RNAase H (Sigma) 25 mg/L for 3 h at 37°C, and then incubation with proteinase K (Sigma) 50 mg/L for 2 h at 60°C. Proteinase K was removed by washing with pyrogen-free water and centrifuging at 105 000 g, after which the LPS fractions were lyophilised and kept at -20°C until used.

Purity of LPS preparations

Samples of all LPS preparations were analysed by SDS-PAGE [22, 23] and by protein quantitation [24] to evaluate the extent of any contamination with protein, as well as by absorbance at 260 nm to determine contamination with DNA [25].

B-cell proliferation

Assays were performed as described previously [17]. Briefly, mice were killed by cervical dislocation and their spleens were removed and homogenised aseptically. Spleen cells were suspended in RPMI 1640 medium containing fetal calf serum 10% v/v, penicillin 100 U/ml, streptomycin 100 mg/L and amphotericin B 0.25 mg/L (all constituents from Sigma) and adjusted to 4 X 10^6 cells/ml. Equal 100-μl portions of cell suspension and LPS preparation (containing 1 μg) were incubated at 37°C in CO2 5% v/v in air in 96-well plates (Nuncelon, Roskilde, Denmark). The optimal concentration of each LPS preparation was determined by testing concentrations of 0.1, 1.0, 10 and 100 μg/ml. After incubation for 72 h, cultures were pulse-labelled with 0.5 μCi of 3H-thymidine (50 Ci/mm; Amersham) and incubation was continued for a further 8 h. The cells were then harvested by filtration on to glass fibre filter paper with a cell harvester, and the associated radioactivity was measured with a liquid scintillation counter (Analyzer 1600; TR Packard). Commercial LPS from *Salmonella* Typhimurium strain SL 1181 (Re mutant) (Sigma) and LPS from a smooth strain were used as positive controls, with RPMI 1640 medium alone as a negative control. All assays were conducted in triplicate.

TNF-α determination

Cells were stimulated with the same protocol (see above) and TNF-α was determined in the supernates of 24-h cell cultures [26] with a Mouse TNF-α ELISA Kit (Genzyme, Cambridge, MA, USA), used according to the manufacturer's directions. The same controls were included.

Splenic index

The ability of LPS preparations to induce an increase in spleen weight was determined by calculating the splenic index. Groups of five female mice were inoculated intraperitoneally with 1 μg of LPS and killed after 4 days. The weight of the animals and of their spleens was determined, and the splenic index was calculated as the ratio between these two parameters (spleen weight:mouse weight) [17]. Positive and negative controls were those described for the cell proliferation assay.

Statistical analysis

Statistical analysis of all the results was by the Tukey test, used in conjuction with the Systat program [27].

Results

Results were obtained with LPS preparations that had been treated with proteinase K to remove protein contamination. Absence of protein in the LPS preparations was demonstrated on gels stained with Coomassie Blue R-250, while the absence of nucleic acid was demonstrated by determining absorbance at 260 nm. All the LPS from the nosocomial isolates examined appeared to contain S-type LPS, as indicated by the ladder-like pattern obtained on SDS-PAGE gels after silver staining (data not shown).

Proliferation assay

All the LPS preparations were mitogenic for B-cells, but differences were observed in their biological activity (Fig. 1). Four isolates (HS-54, HJJA-9, HJJA-7 and HS-4) showed mitogenic activity similar to that of LPS from the smooth strain of *S. Typhimurium*, whereas LPS from the other three isolates (UC-25, HJJA-8 and 95-52) showed mitogenic activity similar...

Each value represents the mean of two readings. A, isolate HS-54; B, HJJA-9; C, HJJA-7; D, UC-25; E, HS-4; F, HJJA-8; G, 95-52; N, negative control (RPMI medium); S, S. Typhimurium (smooth); R, S. Typhimurium (Re mutant).

to that of the Re mutant of S. Typhimurium. The differences in mitogenicity observed between the LPS preparations and the negative control were statistically significant ($p \leq 0.05$) as determined by the Tukey test [27].

TNF-α assay

Six LPS preparations from A. baumannii induced cytokine synthesis in spleen cell cultures (Fig. 2), with induction levels similar to those observed with the LPS from the smooth strain of S. Typhimurium, but higher than those induced by LPS from the Re mutant of S. Typhimurium. However, all these differences were statistically significant when compared with the negative control. Only LPS from isolate HJJA-9 behaved differently in this assay, with no significant induction of TNF-α observed in the spleen cells after challenge.

Splenic index

To assess whether LPS showed activity in vivo, mice were inoculated intraperitoneally with LPS preparations to evaluate induction of spleen growth. Most LPS preparations induced spleen growth, as indicated by the relatively high splenic index observed in comparison with the negative control (Fig. 3), with values obtained with LPS from five A. baumannii isolates being similar to that obtained with LPS from the smooth strain of S. Typhimurium. LPS from isolate HJJA-9 yielded a significantly lower index ($p \leq 0.05$), and LPS from one isolate (HS-4) did not induce spleen growth, even though it corresponds to a smooth type of LPS [18].

Discussion

Although A. baumannii has been studied intensively during the last decade in an attempt to understand its virulence factors, antibiotic resistance mechanisms and epidemiological aspects, the importance of these organisms has only been recognised recently. This study examined the potential contribution of LPS to the virulence of A. baumannii. Previously, Aucken and Pitt [28] reported only R-type LPS from several A. baumannii isolates, but other studies have suggested that Acinetobacter spp. are able to produce S-form LPS [18, 29-31]. If so, LPS may contribute to the

pathogenic properties of these micro-organisms during serious nosocomial infections.

The differences in the ability of LPS from different isolates of A. baumannii to elicit mitogenic activity could be caused by variations in the fatty acid content of lipid A, as has been demonstrated for the LPS of Bacteroides spp. [26]. On the other hand, the high mitogenic activity induced by LPS from isolates HJJA-8 and 95-52 might be the consequence of the experimental quality of the lipid A [26] as well as to differences in the O-antigens [17]. There is a need to further purify lipid A from the rest of the molecule to validate the data obtained with the complete LPS molecule.

TNF-α is considered to be a pivotal cytokine in the host response to endotoxin [32]. The results in this paper indicate that, in this respect, LPS from A. baumannii behaves in a similar fashion to LPS from other gram-negative species. Again, the lack of TNF-α inducing activity of isolate HJJA-9 might result from differences in the structure of lipid A, as has been demonstrated in B. fragilis [33].

In-vivo studies also showed a high biological activity of LPS as an endotoxin. As this activity was homogeneous for the different isolates, it might be speculated that A. baumannii contains a toxic lipid A, mainly because spleen growth is related to this part of the macromolecule [17]. Brade and Galanos [34] compared the biological activities of LPS and lipid A from Acinetobacter with those from Salmonella. In agreement with the present results, these authors also reported that both LPS and lipid A from Acinetobacter exhibited lethal toxicity in mice, pyrogenicity in rabbits, complement inactivation in vitro, a local Shwartzman reaction, mitogenicity for mouse-spleen B lymphocytes and a positive Limulus amoebocyte lysate test [34], with a pattern similar to that obtained with LPS and lipid A from Enterobacteriaceae. Lastly, the lack of activity of LPS from the smooth isolate HS-4 may be a consequence of a lipid A of low toxigenicity or result from the presence of different types of repetitive sugars in the LPS which are not able to modulate the biological activity of the lipid A. The high variability of the O-antigen in the LPS molecules of different clinical isolates has been pointed out by Pantophlet et al. [35]. Overall, the results presented in the present paper suggest an important role for the LPS from nosocomial strains of A. baumannii as a virulence factor in vivo. We conclude that the synthesis of endotoxin might be an important factor responsible for the severity of disease observed during A. baumannii sepsis.
