CLINICAL AND MOLECULAR EPIDEMIOLOGY

Quantitative culture of *Helicobacter pylori* from gastric juice: the potential for transmission

Department of Oral Microbiology, *Gastrointestinal Science Research Unit and †Department of Epidemiology and Medical Statistics, St Bartholomew’s and the Royal London School of Medicine and Dentistry, London, E1 2AD*

The transmission of *Helicobacter pylori* may occur by spread of organisms from gastric juice which has been introduced into the mouth by gastro-oesophageal reflux. The aim of this study was to quantify the load of *H. pylori* present in gastric juice available for transmission. Gastric antral biopsy and gastric juice samples were collected from 108 adult dyspeptic patients undergoing routine upper gastroscopy and the presence of *H. pylori* was determined. In all, 54 (50%) of 108 patients gave positive results in the gastric antral biopsy rapid urease test and for *H. pylori* histology. The gastric juice of 40 (37%) of patients gave positive results for the urease A gene by PCR assay; 34 (31%) of patients were positive by these three tests and *H. pylori* was cultured from the gastric juice of 13 (38%) of these patients. The median count of *H. pylori* in gastric juice was 1.75 × 10⁵ cfu/ml. Viable organisms in gastric juice may lead to transmission of *H. pylori* when refuxed or vomited into the mouth.

Introduction

*Helicobacter pylori* is an important aetiological factor for chronic gastritis and peptic ulcer disease, and is associated with gastric cancer and lymphoma [1–3]. Despite current understanding of the pathophysiology and virulence determinants of this important gastric pathogen, its mode of transmission and infectious dose remain uncertain [4]. Person-to-person spread is the most probable mode of transmission, as no environmental or zoonotic reservoirs have been established. Successful transmission requires that viable organisms are available, but culture of *H. pylori* from sites other than the gastric mucosa, such as the oral cavity and faeces, is rare [5,6]. The incidence of *H. pylori* at these sites has been investigated by PCR, providing inconclusive evidence for either oral–oral or faecal–oral transmission in man [7–9].

*H. pylori* is readily passed from person to person by gastric intubation [10], which usually results in several weeks of acute infection. Gastric juice may play an important role in the natural route of transmission [11].

Materials and methods

*Study subjects and sample collection*

A total of 108 patients (67 male, 41 female; age 17–74 years, mean 46 years) attending the endoscopy unit of the Royal London Hospital, Whitechapel, East London for various reasons, was studied. Patients were chosen at random and ethical permission was obtained for participation in the study. Those patients who had previously received anti-*H. pylori* therapy or were taking acid-suppressing medication were excluded from the study. As much gastric juice as possible (0.5–15 ml, mean 8 ml) was aspirated from the fundic pool of each patient through the endoscope and collected via
a sputum trap at the beginning of the endoscopy procedure. The pH of the gastric juice was measured with pH test strips (Sigma) and immediately neutralised with 0.67 M Tris buffer (pH 7.4) if necessary [19]. The original volume and appearance of the gastric juice were noted. One antral gastric biopsy was taken for the rapid urease test (RUT). Histological examination of one other formalin-fixed antral gastric biopsy stained with the standard haematoxylin and eosin stain was performed by a pathologist experienced in the detection of *H. pylori*. One antral gastric biopsy was collected for culture in 1 ml of glucose 20% w/v from 100 of the patients.

**Bacterial culture from gastric juice and gastric biopsy samples**

Gastric juice samples from all 108 patients were centrifuged at 13 000 rpm in a microcentrifuge for 5 min at room temperature and each deposit was concentrated to a volume of 1 ml. Serial dilutions were made in Brain Heart Infusion (BHI) Broth (Oxoid CM225), and 100-μl volumes were cultured in duplicate on to non-selective BHI Agar (Oxoid CM375) containing defibrinated horse blood 5%, and on to BHI agar containing *H. pylori* selective supplement (Oxoid SR147). All samples were processed within 2 h of collection. Plates were incubated micro-aerobically (Campylobacter gas generating kit, Oxoid BR60) at 37°C for 5 days. Suspected colonies of *H. pylori* were identified by Gram’s stain and positive reactions for catalase, oxidase and urease [20]. Growth was quantified as cfu/ml of gastric juice. The effect of 0.67 M Tris buffer on the growth of *H. pylori* was assessed with National Collection of Type Cultures (NCTC) type strain 11637. Serial dilutions of this strain were made (10^1–10^3/ml) in 0.67 M Tris buffer and left at room temperature for 2 h before being cultured as above. *H. pylori* was cultured from all the concentrations tested. Gastric antral biopsies were homogenised and 100-μl volumes were cultured in duplicate as for the gastric juice samples.

**PCR amplification from gastric juice**

Chromosomal DNA was extracted from the gastric juice of all 108 samples by the cetrimidemethylammonium bromide (CTAB) method according to the DNA miniprep protocol of Wilson [21]. This method is known to remove complex polysaccharides which may inhibit PCR amplification. The primers HPU1 and HPU2 were used to amplify a 411-bp internal fragment of the urease A gene of *H. pylori* as described previously [22]. This assay had been assessed previously for its specificity for the urease A gene of *H. pylori* and found not to cross-react with other Helicobacter species or known urease-producing oral organisms [7]. *H. pylori* NCTC 11637 which had been incubated in Tris buffer (0.67 M) at room temperature for 2 h was also subjected to DNA extraction followed by PCR to determine the minimum detectable number of bacteria with this method. *H. pylori* was detected by PCR at all dilutions tested to a level of 10 cfu/ml.

**Results**

Of the 108 patients evaluated, 54 (50%) were infected with *H. pylori* as assessed by both the RUT and histology (Table 1). All patients who were *H. pylori*-positive by the RUT were also histology-positive, and vice versa. *H. pylori* was cultured from the gastric biopsies of 32 (59%) of these 54 patients, but not from any patient who was RUT and histology negative. The gastric juice of 40 (37%) of 108 patients was *H. pylori* PCR-positive (Fig. 1) of which 28 were cloudy in appearance with mucus and 12 contained bile. Only 34 (31%) of 108 patients were *H. pylori*-positive at both sites, i.e., antral biopsy RUT- and histology-positive and gastric juice PCR-positive. This is explained by the observation that of those patients who were antral biopsy *H. pylori*-positive, 20 (37%) of 54 were gastric

H. pylori was cultured from the gastric juice of 13 (38%) of those 34 patients who were H. pylori positive at both sites as described above (Table 2). All 13 of these gastric juice samples were cloudy in appearance with mucus and initially had a pH of 1–2, except one from a 32-year-old female, which had a pH of 8. This sample contained $8 \times 10^4$ cfu of H. pylori/mL. Colony counts ranged from 1 colony in 15 ml to $3.6 \times 10^5$ cfu/ml of gastric juice (median 1.75 $\times 10^5$ cfu/ml) in these 13 culture-positive samples. H. pylori was not cultured from samples containing bile.

There was no apparent association between culture of H. pylori from gastric juice and disease in these 13 patients (Table 2). H. pylori was also cultured from the gastric biopsies of these 13 patients, but the growth was not quantified. H. pylori was not cultured from the gastric juice of any patient who was either antral biopsy RUT- or histology-negative, or gastric juice PCR-negative. H. pylori was not cultured from the gastric biopsy of any patient sampled who was RUT- and histology-negative, but was cultured from 12 gastric juice PCR-positive and 7 gastric juice PCR-negative patients, in addition to the 13 patients who were gastric juice culture-positive.

Discussion

H. pylori was cultured from the gastric juice of 38% of infected individuals as determined by RUT and histology of antral biopsy and PCR of gastric juice. Previous studies report a wide range (0–67%) of successful culture of H. pylori from gastric juice of infected subjects [15–18], but none has attempted to quantify the numbers of organisms present. The results of the present study indicate that a detectable number (median 1.75 $\times 10^5$ cfu/ml) of viable H. pylori can be cultured from gastric juice. The density of H. pylori in gastric antral biopsies has been calculated as 10^5–10^6 cfu/g [23]. However, this quantity will vary depending on the severity of infection, and not all organisms will remain viable when shed into gastric juice. The infectious dose of H. pylori remains unknown, as data from three volunteer experiments are inconclusive. Marshall [24] achieved successful infection with a recently isolated field strain at a dose of 10^8 organisms in a small liquid feed following the use of antacids. A second volunteer failed to become infected [25] with a dose of 4 $\times 10^7$ organisms of the same field strain after an overnight fast. Infection did succeed in the second volunteer [26] when antacids were used with a different field strain at a dose of 3 $\times 10^7$ organisms. However, these experimental doses may be in excess of the numbers of organisms required to cause natural infection.

Reports of unsuccessful attempts to culture H. pylori from the mouth [27,28] may be due to the organism being present in a non-culturable coccaid form, or as a transient member of the oral microflora. However, detection by PCR indicates that the presence of H. pylori can be demonstrated in the mouths of a significant number of infected individuals [7,8]. If intermittent gastro-oesophageal reflux is responsible for delivery of H. pylori into the mouth, this may account for the variability between studies investigating the detection of the organism by culture and PCR.

Iatrogenic transmission has shown how readily the organism can be passed from patient to patient by gastric secretions which stick to the surfaces of an endoscope [10]. If reflux of gastric contents is important for transmission, the time during which this can successfully take place may be limited to immediately after an episode of reflux, when viable organisms are most likely to be present. Gastro-oesophageal reflux disease (GORD) is often found in patients with antral gastritis, but there are no data to show that these patients are infected with H. pylori.
more frequently than controls, either in adults or children [29]. In contrast, epidemiological data tend to support the hypothesis that *H. pylori* infection may give some protection against reflux disease and adenocarcinoma of the gastro-oesophageal junction [30].

Acute gastritis is often accompanied by a period of temporary hypochlorhydria or achlorhydria [12], which may favour survival of *H. pylori* in gastric juice. In the present study this state was observed in only one of the patients with antral gastritis in whom the gastric juice pH was 8, and 8 x 10^5 cfu of *H. pylori*/ml were isolated. Furthermore, there was no correlation between disease state and those patients from whom *H. pylori* in gastric juice was successfully cultured.

Culture of *H. pylori* from faeces has been achieved [6]. This is surprising, as bile is bactericidal to this organism [20, 31]. *H. pylori* which is shed into gastric juice would not normally survive transit through the intestinal tract because of the toxic effect of bile in the second part of the duodenum. The results of Thomas et al. [6] may be explained by their selection of patients, who were all children with acute gastritis and reduced gastric acid secretion. If transmission of *H. pylori* via faeces does occur then it may be restricted to hypochlorhydric or achlorhydric individuals with acute infection.

It has been suggested that a gastric juice-based PCR assay may be a good alternative to conventional biopsy-based detection techniques [14, 32]. However, the present study showed that 30% of patients with positive biopsy results had negative results in PCR assays of gastric juice. Many patients had a very small volume of fluid in their stomach which was difficult to collect and may have contained numbers of organisms not detectable by the PCR assay employed.

Acquisition of *H. pylori* occurs predominantly in childhood [33], but it is not clear whether transmission takes place primarily between adults and children or from child to child. Although this study was concerned with adult patients, the results suggest that children may also have the potential to spread *H. pylori* via the mouth. It is possible that the numbers of organisms in gastric juice during a first infection, which is more common in children [33], are greater than those found in persons with a chronic infection. Further studies in children would clarify this question.

In conclusion, these results demonstrate that viable *H. pylori* are present in gastric juice for potential transmission via the mouth. Further study of the infectious dose of the organism is required to clarify the significance of this potential.

We thank P. A. Williams for helping to recruit the patients and R. M. Feakins for the histopathology analysis.
