ACTION OF ETHYLENEDIAMINETETRA-ACETIC ACID (EDTA) ON CARBENICILLIN-RESISTANT STRAINS OF PSEUDOMONAS AERUGINOSA

ELAINE BARRETT AND A. W. ASSCHER

CARBENICILLIN is commonly used in the treatment of pseudomonas infections. Unfortunately, recent reports indicate the emergence of resistant strains (Bell and Smith, 1969; Lowbury et al., 1969). Since ethylenediaminetetra-acetic acid (EDTA) reverses the resistance of *Pseudomonas aeruginosa* to several antibiotics *in vitro* (Weiser, Asscher and Wimpenny, 1968), its effect on carbenicillin-resistant strains of *Ps. aeruginosa* was studied.

MATERIALS AND METHODS

Strains of pseudomonas with two different kinds of carbenicillin resistance were studied, namely resistance produced by habituation *in vitro* and the resistance possessed by *Ps. aeruginosa* strains nos. 1822 and 3425, which contain a constitutive episomally mediated carbenicillinase (Fullbrook, Elson and Slocombe, 1970).

**Habituation procedure**

Three hospital strains, which were sensitive to 200 µg per ml of carbenicillin, were subcultured serially on agar containing increasing concentrations of carbenicillin. The minimum inhibitory concentration (MIC) of carbenicillin for these strains was increased from 200 µg per ml to 12,800 µg per ml in seven stages.

**Detection of carbenicillinase activity**

Carbenicillinase activity was detected by estimating the carbenicillin concentration before and after incubation with whole cell and cell-free preparations of the bacterial strain under test. Carbenicillin was estimated by the cup-plate method in tests with *Ps. aeruginosa* no. NCTC10701.

**Measurement of reduction of carbenicillin resistance by EDTA**

The MIC for all strains of pseudomonas was determined in tubes of broth with doubling dilutions of antibiotic and an inoculum size of 10^5 organisms per ml. Parallel estimations were also made in the presence of a subinhibitory concentration of the trisodium salt of EDTA (200 µg per ml). The number of tubes by which the EDTA shifted the MIC of carbenicillin was used as a measure of the reduction of carbenicillin resistance by EDTA.

**Effect of EDTA on carbenicillinase activity**

Cell-free extracts of *Ps. aeruginosa* strains nos. 1822 and 3425 were made by alternate freezing and thawing. These were mixed at a concentration of c. 2 mg dry weight per ml with carbenicillin (0-8 mg per ml) and incubated at 37°C with and without EDTA (20 mg per ml).

*Received 22 Dec. 1971; accepted 9 Feb. 1972.*
Carbenicillin concentrations were measured at 4-min. intervals for 16 min. by the hydroxylamine assay (Batchelor et al., 1961). The rates of decrease of carbenicillin concentration in the presence and absence of EDTA were then compared.

Release of intracellular material

EDTA causes a leakage of material that absorbs light at 260 nm ("260-nm absorbing material") from sensitive bacterial cells (Key, Gray and Wilkinson, 1970). This material represents both the intracellular acid-soluble nucleotide pool and nuclear material (Neu, Ashman and Price, 1967). The rate of release of these substances is a measure of the susceptibility of the bacterial cell to the effect of EDTA and was determined in the following manner. Organisms were grown overnight on nutrient agar slants (Oxoid DST Agar), washed off with physiological saline and centrifuged briefly to remove pieces of pellicle. They were then washed twice, and finally resuspended in physiological saline to a density of $10^9$ organisms per ml; 3 ml of this suspension was added to 20 ml EDTA (725 $\mu$g per ml) in 0.01 M borate buffer (pH 7.4). At intervals of up to 90 min. the action of EDTA was stopped by the addition of excess magnesium chloride. The suspensions were centrifuged for 45 min. at 1000 $g$ and passed through a millipore filter of pore size 0.45 $\mu$. The extinction at 260 nm was then read on an SP1800 spectrophotometer.

**RESULTS**

**Strains made resistant to carbenicillin by habituation**

Carbenicillinase activity was not detected in any of these strains. The effect of EDTA on the MIC of carbenicillin for one of the habituated strains at the

* $\mu$g per ml carbenicillin in the absence of EDTA
various stages of development of its resistance is shown in fig. 1. EDTA produces a virtually constant (2- to 3-tube) reduction of the MIC of carbenicillin at all stages of the development of habituated resistance. The results obtained with the two other strains that had been habituated in vitro were identical. High concentrations of EDTA are bactericidal. It is possible, therefore, that addition of the effects of EDTA and carbenicillin accounts for the constancy of the reduction of habituated carbenicillin resistance by EDTA. If this were so, it might be expected that the habituated resistant strains would be equally susceptible to a fixed dose of EDTA at all stages of the development of their resistance. This was not the case. As shown in fig. 2, the rates of release of 260-nm absorbing material were found to be significantly slower (P<0.001) from the habituated resistant strains than from their sensitive counterparts. Thus pseudomonas strains trained to tolerate carbenicillin are also more resistant to the action of EDTA, and the constant degree of reduction of carbenicillin resistance by EDTA cannot be attributed to a summation of the effects of EDTA and carbenicillin but must be ascribed to a synergistic effect of the EDTA-carbenicillin combination.

Carbenicillinase-producing resistant strains

It can be seen from fig. 1 that EDTA caused a marked (5-tube) reduction of carbenicillin resistance in one of these strains (Ps. aeruginosa no. 1822), whereas in the other (Ps. aeruginosa no. 3425) the reduction was less and fell within the range observed in the habituated resistant strains. EDTA had no effect on carbenicillinase activity, and the rate of release of 260-nm absorbing material from the two strains did not differ significantly.
DISCUSSION

EDTA reduces carbenicillin resistance of *Ps. aeruginosa* irrespective of its degree or type. This may depend on the increase in bacterial permeability to penicillin produced by EDTA which enables more carbenicillin to reach its site of action (Hamilton-Miller, 1966). The development of habituated carbenicillin resistance was found to be associated with a reduction of the sensitivity of the bacterial cells to EDTA. This observation may clarify the mechanism of resistance produced by habituation *in vitro*. EDTA removes protein and lipopolysaccharide from the cell wall of *Ps. aeruginosa* (Rogers, Gilleland and Eagon, 1969). In *Escherichia coli*, loss of polysaccharide from the cell wall is associated with an increase in permeability, and resistance to EDTA is due to a change in the type of cell-wall lipopolysaccharide (Voll and Leive, 1970). Because the emergence of carbenicillin resistance on habituation *in vitro* is accompanied by the development of resistance to EDTA, it seems likely that habituated carbenicillin resistance is due to a change in type or increase in amount of cell wall lipopolysaccharide. Such a change in cell-wall composition might well form the basis of the “intrinsic” type of resistance shown by *Ps. aeruginosa* to carbenicillin (Sykes and Richmond, 1971).

Since EDTA does not affect the carbenicillinase activity of *Ps. aeruginosa* strains no. 1822 and 3425, it seems likely that the reduction of carbenicillin resistance produced by EDTA in these strains, as in the habituated strains, also depends on an increase in bacterial permeability. Following exposure to EDTA, the rate of release of 260-nm absorbing substances from both of the carbenicillinase producing strains was similar. The more marked reversal of carbenicillin resistance observed in strain no. 1822 as compared with no. 3425 is probably accounted for by the observation that no. 1822 produces only a quarter of the carbenicillinase produced by no. 3425 (Fullbrook et al., 1970). Thus for a given increase in bacterial permeability produced by EDTA, the amount of carbenicillin reaching the carbenicillin “receptors” would be greater in strain no. 1822, since less of the drug would be destroyed after entry into the bacterial cell.

SUMMARY

Sub-inhibitory concentrations of EDTA reduce the resistance of strains of *Pseudomonas aeruginosa* to carbenicillin *in vitro*. With strains made resistant by habituation, the extent of the reduction of carbenicillin resistance produced by a fixed subinhibitory dose of EDTA (200 µg per ml) did not vary with the degree of resistance even though the development of this habituated resistance was associated with a loss of sensitivity of the bacterial cells to EDTA. This suggests (1) that the reduction of habituated carbenicillin resistance by EDTA is due to a synergistic effect of the EDTA-carbenicillin combination, and (2) that the development of habituated carbenicillin resistance in *Ps. aeruginosa* is due to a change in type or amount, or in both, of cell-wall lipopolysaccharide.

In carbenicillinase-producing resistant strains of *Ps. aeruginosa*, the amount of reduction of carbenicillin resistance by EDTA is variable and appears to be
inversely related to the quantity of carbenicillinase produced by the bacterial strain.

We are grateful to Dr E. A. P. Croydon of Beecham Research Laboratories for providing cultures of *Ps. aeruginosa* no. 1822 and 3425.
