Identification of a 43-kDa outer-membrane protein as an adhesin in Aeromonas caviae

Departamento de Microbiologia e Imunologia, Faculdade de Ciências Médicas, *Departamento de Histologia e Embriologia, Instituto de Biologia, Universidade do Estado do Rio de Janeiro, Av. 28 de Setembro, 87 -Fundos, 3º andar, Vila Isabel, RJ 20551-030 and †Departamento de Microbiologia Geral, Instituto de Microbiologia Prof. Paulo de Góes,Universidade Federal do Rio de Janeiro, CCS, Bloco I, Ilha do Fundão, RJ, Brazil

Aeromonas spp. are associated with intestinal and extra-intestinal infections. However, the virulence factors of A. caviae remain, for the most part, poorly known. This study examined the interactions involved in the adherence of A. caviae isolates Ae56, Ae391 and Ae398 to HEp-2 cells. All strains expressed high levels of aggregative adherence. Maximum adhesion occurred with bacteria grown at 22°C, but transmission electron microscopy did not reveal the presence of fimbrial structures on the bacterial cell surface. Outer-membrane proteins (OMPs) extracted from isolate Ae398, grown at 22°C and 37°C, showed similar SDS-PAGE protein profiles. Most proteins were <60 kDa. A major 43-kDa protein was seen only in the boiled OMP extract. The biotinylated 43-kDa protein bound specifically to HEp-2 cells. Microbeads coated with the 43-kDa protein were also adherent to HEp-2 cells, and anti-43-kDa protein antibody blocked adherence of 43-kDa protein-coated latex beads. These data suggest that the 43-kDa OMP functions as an adhesin in A. caviae.

Introduction

Aeromonas spp. comprise a widespread group of gram-negative bacteria that can be isolated from many sources such as food, drinking water, sewage, environmental water and human clinical specimens [1–3]. Virulence mechanisms are not well understood and confusion over the taxonomy of the genus has compounded difficulties in the identification of potential disease-causing strains. However, substantial evidence points to Aeromonas spp. as the causative agents of sporadic diarrhoea, dysentery and extra-intestinal infections that may be life-threatening [4, 5]. Two hybridisation groups (HGs), A. hydrophila (HG1) and A. veronii biovar sobria (HG8) were thought to be the main causes of aeromonas-associated illness. However, some investigations also implicate A. caviae (HG4) as a significant enteropathogen [6, 7]. It has been recognised that adherence to host cells is an important step in the pathogenesis of enteropathogenic bacteria, including Aeromonas spp. [8–11]. Although recent studies indicate that some filamentous structures, outer-membrane proteins (OMPs) and lipopolysaccharide (LPS) could be intestinal adhesins, the colonisation mechanisms of enteropathogenic Aeromonas strains are poorly characterised, especially in A. caviae [12–15]. The pili of aeromonads have been described by morphological criteria as short, rigid (S/R) and long, wavy (L/W) structures. S/R pili are common and numerous among environmental isolates. In contrast, L/W pili are few in number, but are the dominant type observed on clinical strains [8]. L/W pili have been identified as aeromonas colonisation factors and also as haemagglutinins [12, 13]. Furthermore, an A6-type haemagglutinin (A6-HAG) from A. hydrophila has been reported as a possible colonisation factor. A6-HAG is a 43-kDa OMP that binds to H antigen expressed on the surface of most human erythrocytes [16, 17]. In this study OMPs were investigated as possible colonisation factors in A. caviae adherence to HEp-2 cells.

Materials and methods

Bacterial strains and culture conditions

Three clinical isolates of A. caviae (Ae56, Ae391 and Ae398) from children with gastro-enteritis were studied. They were isolated in the Bacteriology Department

Received 12 June 2000; accepted 14 Sept. 2000.

Adhesion to HEP-2 cells

HEP-2 cells (ATCC CCL23), derived from human epidermoid larynx carcinoma, were grown under standard conditions in air with CO₂ 5% at 37°C in Eagle's Minimal Essential Medium (MEM, Sigma) supplemented with fetal calf serum (FCS; Gibco BRL, NY, USA) 5%. For the qualitative adhesion assay, HEP-2 cells were grown to semi-confluency for 24 h on circular glass coverslips (diameter 12 mm) in 24-well tissue-culture plates (Nalgene Nunc International, Denmark). Bacteria grown in TSB at 22°C or 37°C were harvested by low speed centrifugation, washed twice in 10 mM Na-phosphate-buffered saline, pH 7.4 (PBS) and resuspended in MEM containing FCS 5%. One ml of bacterial suspension, containing 10⁵ cfu (OD₅₆₀ 0.2), was added to duplicate coverslip cultures of HEP-2 cells. The infected monolayers were incubated at 37°C for 90 min in air with CO₂ 5%. Non-adherent bacteria were removed from monolayers by washing three times with PBS. The cells were fixed with methanol-acetic acid (3:1) for 15 min and stained with Giemsa 10% for 1 h. The coverslips were mounted on glass slides and viewed by light microscopy [8]. For the quantitative adhesion assay, HEP-2 cells were grown to confluency for 48 h in 24-well tissue-culture plates. Bacterial suspensions, prepared as described above, were inoculated on to the HEP-2 monolayers. After incubation at 37°C for 90 min in air with CO₂ 5%, the monolayers were washed three times with PBS. Then 200 μl of Triton X-100 1% in PBS were added to each well and the plates were rocked at 37°C for 30 min. MEM (800 μl) was added and pipetted up and down vigorously to thoroughly mix the bacteria and lyse the HEP-2 cells. The suspensions were diluted serially in PBS and plated on to Mueller-Hinton Agar to determine the number of cell-associated bacteria. Adherence was expressed as the percentage of the inoculum recovered from the HEP-2 cells after incubation for 90 min.

OMP extraction

For OMP extraction, A. caviae EA398 was grown at both 22°C for 48 h and 37°C for 24 h. The cultures were centrifuged at low speed for 15 min at 4°C. The bacterial pellet was resuspended in 70 ml of a solution containing 10 mM Tris-HCl, pH 7.8, 5 mM EDTA, pH 7.8, and 1 mM β-mercaptoethanol (Sigma). The cells were disrupted by four 15-s bursts at the full power of an ultrasonic disintegrator. Cell debris was removed by low-speed centrifugation (2000 g, 20 min) and membranes were pelleted from the supernatant fraction by centrifugation at 100 000 g for 1 h at 4°C. The membrane pellet was resuspended in 20 ml of Sarkosyl (Sigma) 0.5% and 1 mM β-mercaptoethanol in distilled water and incubated at 4°C overnight. The suspension was then centrifuged at 100 000 g for 1 h at 4°C and the final outer-membrane pellet was resuspended in 10 mM Tris-HCl buffer, pH 7.8 [19]. The protein content of the OMP suspension was determined by the modified method of Lowry [20] with bovine serum albumin (BSA, Sigma) as standard.

Biotinylation of OMPs

The OMPs were dialysed against 100 mM sodium bicarbonate solution (pH 9.0) at 4°C overnight, then 10 μl of 100 mM biotin (Sigma) were added to 1 ml of OMP solution (1 mg/ml) at 4°C for 1 h. The OMP solution was then dialysed against PBS at 4°C overnight [21].

HEP-2 cell-associated biotinylated OMP assay

Biotinylated OMP solution prepared as described above was added to confluent HEP-2 monolayers in a 24-well tissue-culture plate. After incubation for 90 min at 37°C in air with CO₂ 5%, the monolayers were washed three times in PBS. Lysis buffer (200 μl) pH 7.5 – 25 mM Tris-HCl, 250 mM NaCl, 5 mM EDTA, 1 mM MgCl₂, phenylmethylsulphonylfluoride (PMSF) 100 μg/ml and Igepal (Sigma) 0.1% – were added to each well and rocked at 4°C for 30 min. The lysed cells were removed by centrifugation at 5000 g at 4°C for 15 min. The supernate was submitted to SDS-PAGE and analysed by the Western blot technique.

SDS-PAGE and Western blot analysis

SDS-PAGE was performed as described by Laemmli [22] with a discontinuous acrylamide 10% gel (Mini-protein II, BioRad). Five μl of OMP extract (1 mg/ml) or 5 μl of HEP-2 cell-associated biotinylated OMPs (1 mg/ml) were mixed with an equal volume of 2 × SDS-PAGE sample buffer (125 mM Tris-HCl, SDS 4%, glycerol 20%, β-mercaptoethanol 2%, bromophenol blue 0.002%) and boiled for 5 min before...
Electrophoresis. Separated proteins in the gel were stained with Coomassie Brilliant Blue in methanol 40%, acetic acid 10% in distilled water. In some analyses, the OMPs were mixed within 2 × SDS-PAGE sample buffer without β-mercaptoethanol and were not boiled. After SDS-PAGE, HEP-2 cell-associated biotinylated OMPs were transferred to a nitrocellulose membrane in a Mini-Transblot Cell (BioRad) by electrophoresis in running buffer, pH 8.3 (25 mM Tris, 192 mM glycine, SDS 1%) for 90 min at 100 mV/400 mA [23]. Membranes were blocked with skim milk 5% in Tris-buffered saline, pH 7.5 (TTBS; 20 mM Tris, 500 mM NaCl, Tween-20 0.05%) for 2 h, washed three times in TTBS and incubated with 1 in 5000 streptavidin-peroxidase (Sigma) for 30 min. After washing, they were developed in a solution of H₂O₂ 0.3%, 3-3′ diaminobenzidine 1 mg/ml, imidazole (Sigma) 1 mg/ml.

43-kDa OMP isolation and antibody production

SDS-PAGE of OMP extract (500 µg) was performed as described above. The 43-kDa protein was cut out and eluted from gel slices with a Electro-Eluter (Model 422, BioRad) and the running buffer, pH 8.3, at 20 mA for 6 h. The 43-kDa protein concentration was assayed as described previously [20]. A New Zealand White rabbit was immunised by multiple subcutaneous injections with 150 µg of purified 43-kDa OMP emulsified with complete Freund’s adjuvant (Sigma). Subsequently, three intramuscular injections were given weekly in incomplete Freund’s adjuvant (Sigma). The rabbit was bled directly via the heart at day 10 after the last injection. The antiserum was pooled and stored at –20°C until used [24]. The IgG fraction of the antiserum was obtained by multiple salting out with 33% saturated ammonium sulphate and purified on a column of Superose (10/30) by high-performance liquid chromatography (HPLC; Pharmacia LKB Biotechnology, Upsala, Sweden) [25]. The purification procedure was monitored by SDS-PAGE analysis and the concentration of IgG antibody was determined by absorbance at 280 nm. The specificity of the IgG for the 43-kDa OMP was checked by the Ouchterlony immunodiffusion method [25].

HEP-2 cell-associated 43-kDa OMP assay

Carboxylated microspheres (1 µm, Sigma) were coated with the 43-kDa OMP or BSA. The concentration of coated beads was c. 1.8 × 10¹⁰ beads/ml, and the amounts of 43-kDa OMP and BSA bound to each microsphere were estimated as 20 fg [26]. Then, 50 µl of a suspension of protein-coated beads were added to HEP-2 semi-confluent monolayers in 24-well tissue culture plates. After incubation at 37°C for 90 min in air with CO₂ 5%, non-adherent beads were removed from monolayers by washing three times in PBS. The cells were fixed with glutaraldehyde (Merek) 0.2% and viewed by light microscopy. For adherence inhibition assays, 43-kDa OMP-coated beads (1.8 × 10¹⁰ beads/ml) were pretreated with anti-43-kDa OMP antibody (200 µg/ml) at 37°C for 1 h and added to the HEP-2 cell monolayers. In the other assay, HEP-2 cells were pretreated with OMP solution (1 mg/ml) and exposed to the 43-kDa OMP-coated beads. The adhesion assays were performed as described above.

Electron microscopy

All three A. caviae strains were examined for the presence of fimbriae by transmission electron microscopy (TEM). Cell suspensions were fixed in phosphate-buffered glutaraldehyde 0.2% (pH 7.2) at 4°C for 15 min and a drop was placed on formvar-coated copper grids (150 mesh, Sigma) for 5 min. The grids were negatively stained with potassium phosphotungstate 1%, washed with water for 1 min, dried and then viewed in a Zeiss 906 transmission electron microscope. For immunolabelling, the grids were inoculated in the presence of BSA 5% w/v in Tris buffer, pH 8.2 (20 mM Tris, Tween 20 0.05%) for 30 min to prevent non-specific labelling, and then treated with anti-43-kDa OMP antibody (1 in 40 dilution) for 1 h at room temperature, washed three times in PBS and then incubated in the presence of 5 nm gold-labelled goat anti-rabbit IgG (1 in 20 dilution) for 30 min at room temperature. After incubation, the grids were washed in the same buffer, negatively stained as before and viewed as above. Grids treated with pre-immune serum (1 in 40 dilution) were used as a control.

Results

Non-fimbrial adherence to HEP-2 cells

A. caviae isolates (Ae56, Ae391, Ae398) showed a higher percentage of adherence than E. coli DH5α to HEP-2 cells (Table 1). All isolates formed small clusters of aggregated bacteria (>10 bacteria/cell) on the cell surface. Bacterial aggregates adhered to cell monolayers with a typical ‘stacked-brick’ appearance (Fig. 1). All the A. caviae isolates were more adherent to HEP-2 cells when the bacteria were grown at 22°C than when they were grown at 37°C. In quantitative assays, a mean of 32.5% and 3.4% of the initial inoculum of strains grown at 22°C and 37°C, respectively, adhered to HEP-2 cells after incubation for 30 min (Table 1). The results of electron microscopy showed that all the A. caviae isolates, whether grown at 37°C or 22°C, did not form fimbrial structures on the bacterial cell surface when compared with the fimbriate control A. hydrophila Ac7. Fig. 2 shows an electron micrograph of A. caviae isolate Ae398 grown at 22°C for 48 h.

Purification of OMPs and binding to HEP-2 cells

Preparation of OMPs by the Sarksyl method was found to be effective for the A. caviae isolates; c. 10–

20 mg and 2–4 mg of OMPs were obtained from 6 L of bacterial culture incubated at 22°C for 48 h and at 37°C for 24 h, respectively. No qualitative differences were observed in the OMP profiles by SDS-PAGE of A. caviae Ae398 grown at 22°C or 37°C (Fig. 3a).

Most proteins were <60 kDa, the predominant band being a 43-kDa protein. This 43-kDa protein was observed only in the boiled OMPs and was not influenced by β-mercaptoethanol treatment (Fig. 3b). Western blotting analysis revealed specific binding of the biotinylated OMP extract to HEP-2 cells. Only the 43-kDa OMP of _A. caviae_ bound selectively to HEP-2 cell surface molecules (Fig. 4).

**Adhesion of 43-kDa OMP-coated beads to HEP-2 cells**

Each 1 mg of OMP extract yielded c. 150 μg of purified 43-kDa protein. The 43-kDa OMP-coated beads adhered to HEP-2 cells by interacting with the cell surface. The attachment was confirmed by light microscopy (Fig. 5a). Control BSA-coated beads did not interact with HEP-2 cells, even when high concentrations of beads (10^{10} beads/ml) were used (data not shown). The 43-kDa OMP-coated beads did not interact with the cell surface when they were pretreated with anti-43-kDa OMP antibodies (Fig. 5b). Similar results were obtained with HEP-2 cells pretreated with OMP extract solution, confirming the specificity of 43-kDa OMP binding to cell surface (data not shown).

**Distribution and immunolocalisation of 43-kDa OMP on bacteria**

A uniform distribution of the 43-kDa OMP over the _A. caviae_ cell surface was demonstrated by immunogold staining (Fig. 6). The 43-kDa OMP was observed on the cell surface of all the _A. caviae_ isolates tested. In the absence of anti-43-kDa OMP antibodies, gold-labelled goat anti-rabbit IgG did not interact with the bacterial cell surface.

**Fig. 5.** Light microscopy (×520) showing (a) the interaction of 43-kDa OMP-coated beads with HEP-2 cells (inset ×1030); (b) inhibition of 43-kDa OMP-coated bead adherence by anti-43-kDa OMP antibody.

**Fig. 6.** Immunogold electron microscopy (IEM) of _A. caviae_ isolate Ae398, stained with anti-43-kDa OMP antibody. IEM demonstrated a uniform distribution of the 43-kDa protein over the cell surface.
Discussion

Although attachment to the intestinal mucosa is likely to be an important pathogenic stage for diarrhoea-causing bacteria, little is known about the adhesive mechanisms of aeromonads. Studies have shown a correlation between bacterial adherence in vitro and infectivity in vivo [10]. Some studies have described adherence of *Aeromonas* strains to cultured cells such as HEP-2, Caco-2 and INT-407 [9, 10, 27]. Although it cannot be assumed that HEP-2 cells, derived from human laryngeal epithelial carcinoma, possess surface receptors identical to these of human enterocytes, a correlation between the high-level adherence to HEP-2 cells and aeromonas enteropathogenicity has been observed [9, 28]. On the other hand, *A. caviae* strains were also reported to express weak adhesive properties to HEP-2 cells [8, 28]. The present study demonstrated that all the *A. caviae* isolates tested showed a high percentage of adherence to HEP-2 cells. The high percentage of isolation of *A. caviae* from children with gastro-enteritis may reflect the enteropathogenic potential of this species. Bacterial growth temperature influenced *A. caviae* adherence to HEP-2 cells and quantitative expression of the 43-kDa OMP on the cell surface. All the *A. caviae* isolates showed greater adherence when grown at 22°C than at 37°C, as observed similarly with *A. veronii* bivar sobria strains [9]. This difference correlated with higher expression of the 43-kDa OMP at 22°C than at 37°C.

The aggregative adherence pattern was first observed in *E. coli* strains. Enterodohere-inducible (EA-Agg) *E. coli* have been incriminated as important agents of diarrhoea, inducing damage to the intestinal epithelium, and characterised by a shortening of the villi, haemorrhagic necrosis of the villus tips and a mild inflammatory submucosa response [29]. Previous investigations have also described the aggregative adherence pattern to HEP-2 and Caco-2 cells for *Aeromonas* spp. [11, 30]. All the *A. caviae* strains investigated in this study exhibited the aggregative adherence pattern and readily formed aggregates able to adhere to HEP-2 cells with a stacked-brick appearance.

Filamentous structures were described as colonisation factors in *A. hydrophila* and *A. veronii* bivar sobria strains [13]. L/W pili, bundle-forming pili and filamentous networks showed maximal expression under the same conditions (22°C for 48 h) as those that induce high adherence to cultured cells [9, 31]. However, TEM did not reveal the presence of fimbral structures on the cell surface of highly adherent *A. caviae* strains grown under these conditions. The data suggested that instead of fimbrae, OMPs might be involved in the adherence process. Merino et al. suggested that LPS and OMP might be other important adhesins for binding of *Aeromonas* strains to HEP-2 cells [15]. The findings of the present study are at variance with that described recently of type IV pili in *A. caviae* strains isolated from clinical sources in Australia [32], possibly because they are from a different geographic location [6]. Furthermore, it is possible that, if filamentous structures are expressed on the cell surface of *A. caviae*, they exist only in very small numbers under the conditions tested here. On the other hand, adhesion of the Australian *A. caviae* strains to HEP-2 cells was only in part mediated by filamentous structures [32].

OMPs from *A. caviae* Ae398, grown at 22°C and 37°C, showed similar protein profiles in SDS-PAGE. The 43-kDa OMP was observed only in boiled extract of OMPs, independently of the presence of β-mercaptoethanol, indicating either a link of this 43-kDa protein to a heavier molecular structure or its aggregation to other proteins.

*A. hydrophila* strain A6 was found to produce a haemagglutinin that was inhibited by l-fucose [16]. The haemagglutinin was also described as a pore-forming 43-kDa OMP in artificial planar bilayer membranes [17, 33]. The 43-kDa OMP from *A. caviae* isolate Ae398 may also be a pore-forming OMP. However, none of the *A. caviae* isolates showed either haemagglutinating activity to human erythrocytes or l-fucose-sensitive adherence to HEP-2 cells (data not shown). Interaction of OMP extract with HEP-2 cells revealed a specific binding of the 43-kDa protein to the HEP-2 cell surface, suggesting that this protein could be an adhesin of *A. caviae*. Furthermore, the 43-kDa OMP-coated beads adhered to the HEP-2 cell surface. The 43-kDa OMP exhibited a uniform distribution over the cell surface of all *A. caviae* isolates tested. Both anti-43-kDa OMP antibody and OMP extract inhibited adherence of 43-kDa protein-coated latex beads. From these experiments, it was concluded that a 43-kDa OMP is involved in *A. caviae* adherence. Complementary studies are currently in progress to enhance understanding of the role of the 43-kDa protein and other structures in the adherence of *A. caviae* to host cells.

We are grateful to CNPq, CAPES, FAPERJ and SR2/UE RJ for providing financial support and to Dr João R.C. Andrade and Dr Maria Cristina M. Plotkowski, Faculdade de Ciências Médicas, Universidade do Estado do Rio de Janeiro for HEP-2 cells, some reagents and helpful comments.
