Blood-brain barrier (BBB) permeability during sepsis with Escherichia coli or Streptococcus pneumoniae was examined in a mouse model and measured by a circulating β-galactosidase tracer. The leakage of brain microvascular vessels during sepsis was confirmed by transmission electron microscopic examination of brain tissues stained with horseradish peroxidase. The increase of BBB permeability induced by E. coli and S. pneumoniae, which was maximal at 3 h and 12 h after injection, respectively, was transient because of rapid clearance of the bacteria from the blood. Tumour necrosis factor-α (TNF-α) was stained on microvascular vessels of the brain during sepsis and intravenous injection of recombinant TNF-α also increased the BBB permeability. The increase in BBB permeability induced by either E. coli or S. pneumoniae could be inhibited by anti-TNF-α antibody. It was concluded that circulating TNF-α generated during sepsis induced the increase in BBB permeability.

Introduction

The incidence of septic shock, one of the commonest causes of mortality in clinical bacterial infection, is increasing steadily – especially in intensive care units – despite the availability of effective antibiotic treatment [1–3]. Cytokines such as tumour necrosis factor-α (TNF-α) and interleukin-1 (IL-1) are released in large amounts by monocytes, macrophages and other leucocytes in response to gram-negative or gram-positive bacterial substances and play a critical role in the pathogenesis of septic shock [4–8]. Both gram-negative and gram-positive bacteria-induced sepsis also cause apoptosis of the thymocytes, and TNF-α involvement is common to both [9]. In addition to cytokine involvement in septic shock, there is evidence that overactivation of macrophages alters endothelial permeability in multiple organs during septic shock [10]. However, change of the blood-brain barrier (BBB) during sepsis was not clearly demonstrated.

The central nervous system (CNS) of mammals is considered to be an immunologically privileged site because of the lack of lymphatic drainage and its separation from the blood by the BBB [11, 12]. The BBB plays an important role in controlling the access of inflammatory cells and macromolecules into the brain by virtue of its selective permeability on its microvascular endothelial cells such as the presence of tight junctions, no formation of pinocytotic vesicles and wrapping by astrocytes [11–13]. Bacterial meningitis is associated with damage to the BBB [14]. Clinical evidence also suggests that bacterial meningitis results from bacteraemia or sepsis [15, 16]. It was found previously that TNF-α-induced cyclooxygenase 2 was responsible for increased BBB permeability in Escherichia coli-induced meningitis [17]. This study used a tracer to quantify the increase of BBB permeability [17, 18], and investigated the effect of gram-negative and gram-positive bacteria-induced sepsis on BBB permeability.

Materials and methods

Mice

C57BL/6 (B6) mice were purchased from either Jackson Laboratory, Bar Harbor, ME, USA or Charles River Japan (Atsugi, Japan). They were maintained on standard laboratory chow and water ad libitum in our animal centre and raised and cared for following the guidelines of the National Science Council of the Republic of China. Female 8–12-week-old mice were used in all experiments.
Induction of sepsis

E. coli ATCC10536 and a Streptococcus pneumoniae strain of serotype 14, a clinical isolate from the National Cheng Kung University Hospital, were cultured in Luria-Bertani (LB) Broth and Todd Hewitt Broth (Difco), respectively, for 12 h at 37°C and were subcultured into fresh medium for another 3 h. The concentration of bacteria was determined with a spectrophotometer with an OD_{600} of 1 equal to 10^8 cfu/ml for E. coli and 10^7 cfu/ml for S. pneumoniae. The 100% lethal dose (LD100) of E. coli and S. pneumoniae by peripheral intravenous (i.v.) injection in B6 mice was 2 × 10^8 and 1 × 10^9 cells, respectively. For the induction of sepsis, groups of four mice were inoculated intraperitoneally (i.p.) with 100 μl of a suspension containing 1 × 10^7 cells (per mouse) in saline. In the antibody inhibition experiment, 40 μg of rabbit anti-TNF-α antiserum (Genzyme Diagnostics, Cambridge, MA, USA) were administered i.v. simultaneously.

Detection of increased vasopermeability of BBB by M4 tracer with β-galactosidase activity

An E. coli mutant (M4) that expressed β-galactosidase constitutively was used as a tracer to detect alterations in the vasopermeability of BBB [17, 18]. M4 was selected from E. coli K-12 cultured in M63 medium (KH₂PO₄ 0.3%, K₂HPO₄ 0.7%, (NH₄)₂SO₄ 0.2%, 0.1 mM FeSO₄) containing lactose 0.2%, vitamin B₁ 0.002%, 1 mM MgSO₄, isoleucine-leucine-valine 0.001% and 5-bromo-4-chloro-3-indolyl-β-D-galacto-pyranoside (X-Gal) 0.002%. The M4 mutant expressed β-galactosidase constitutively and had a characteristic blue colony on medium containing X-Gal without inducer. Strain M4 was avirulent (LD50 > 2 × 10^9 cells) for mice and was removed from the circulation within 2 h of i.v. injection. No alteration of BBB permeability was found within 30 min after i.v. injection of 2 × 10⁶ M4 cells. To determine the timing of giving strain M4, more M4 tracers were detected in the brain at 2 min after i.v. injection than at 10 min or

Fig. 1. Detection of the peripheral M4 tracer in brain by X-Gal staining in E. coli-induced sepsis. Groups of four B6 mice were inoculated i.p. with E. coli 1 × 10⁷ cells/mouse and killed at various time points after injection. PBS was used as a control. The M4 tracers (2 × 10⁹ cells) were injected i.v. 2 min before each animal was killed; 4-μm sections of frozen brain tissues were stained with X-Gal as described in Materials and methods. (a) PBS, 3 h; (b) 1 h; (c) 3 h; (d) 6 h (×350). Arrow indicates the X-Gal-positive M4.
30 min (data not shown). Therefore, strain M4 was an inert tracer at 2 min after injection. UV-inactivated strain M4 behaved in the same way as viable strain M4, but the latter could be amplified to quantify the degree of increased BBB permeability. To each mouse into which *E. coli* or *S. pneumoniae* was injected, 2 × 10⁸ cells of the M4 tracer in 0.1 ml of phosphate-buffered saline (PBS) were given i.v. 2 min before the mice were killed. The brains were removed, cryosectioned and fixed in glutaraldehyde (Merck GmbH, Darmstadt, Germany) 0.2%. The M4 tracers in the tissues were detected by X-Gal staining (X-Gal 1 mg/ml in 20 mM potassium ferricyanide, 20 mM potassium ferrocyanide and 2 mM magnesium chloride at 37°C for 2 h). To quantify the degree of BBB opening, the brains were removed aseptically after perfusion via cardiac puncture with PBS and were homogenised with gelatin 3% in PBS. The samples were serially diluted and cultured at 37°C overnight. The number of X-Gal-positive cfu was quantified and expressed as the mean and SD/mouse. Experiments were performed three times with similar results and one is presented.

**Immunohistochemistry**

Groups of four mice were killed by perfusion via cardiac puncture with PBS. The brains were removed, embedded in OCT compound (Miles, Elkhart, IN, USA) and frozen in liquid nitrogen. Sections were cut (4 µm), fixed with ice-cold acetone for 3 min and then stained with rat anti-mTNF-α monoclonal antibody (MAb) (MP6-XT3; PharMingen, San Diego, CA, USA). The second antibody used was peroxidase-conjugated sheep anti-rat immunoglobulin G (IgG) (Kirkegaard & Perry Laboratory, Gaithersburg, MD, USA). A peroxidase stain of a reddish-brown colour was developed with an aminoethyl carbazole substrate kit (Zymed Laboratories, San Francisco, CA, USA) [17–19].

**Transmission electron microscopy**

Mice under anaesthesia were perfused through the heart with saline followed by 100–130 ml of fixative containing paraformaldehyde 4% and glutaraldehyde 0.5% in PBS. The brains were removed and 40-µm sections of the cortex were cut. After several washes, sections were treated with osmium tetroxide 1–1.5% in 0.1 M sodium cacodylate solution at 4°C for 1–2 h, dehydrated in a graded series of ethanol, cleared in propylene oxide and flat-embedded in plastic. The sections were examined with an electron microscope (JEOL JEM-1200EX) at 75 kV [20]. To determine the microscopic change of BBB, each mouse was given horseradish peroxidase (type IV, Sigma) 5 mg i.v. 10 min before it was killed. The sections were incubated with diaminobenzidine solution for 15–30 min according to the standard protocol [21] to localise the exogenous peroxidase activity.

**Detection of remnant bacteria in the blood**

Groups of four mice were inoculated i.p. with (per mouse) 1 × 10⁷ cells of *E. coli* or *S. pneumoniae*. At various times after injection, blood was collected into heparin. The samples were serially diluted and were poured into LB agar (for *E. coli*) or blood agar (for *S. pneumoniae*) and incubated at 37°C overnight. The number of cfu was quantified and expressed as the mean and SD/mouse.

The significance of differences between treatment groups was determined by Student's *t* test.

**Results**

Detection of increased BBB permeability with the M4 tracer in *E. coli* and *S. pneumoniae*-induced sepsis

Intravenous injection of *E. coli* or *S. pneumoniae* induced sepsis and septic shock. An increase in BBB vasopermeability during the development of sepsis was detected with the M4 tracer that expressed β-galactosidase constitutively. The results showed that X-Gal-stained M4 cells were deposited in the parenchyma, beside the brain venules, as early as 1 h (Fig. 1b), and more were found in the parenchyma and meninges at 3 h than at 1 h or 6 h after injection of *E. coli* (Fig. 1c, d). However, the BBB was impermeable to the tracer at 9 h after injection (data not shown). The presence of X-Gal-positive M4 in the parenchyma of the brain indicated that the vasopermeability of BBB was increased sufficiently to allow a macromolecule such as *E. coli* M4 to cross the BBB. Nevertheless, there was no cell infiltration in the brain. To quantify the increase of BBB permeability, the numbers of M4 cells deposited in the brain were counted. As shown in Fig. 2a, the permeability of the BBB increased from 1 h to 3 h, then decreased at 6 h to a level similar to that of the PBS control (Fig. 2a). The maximal opening of the BBB was found at 3 h after injection, and the degree of opening was dependent upon the injected dose of *E. coli* (Fig. 2b).

The effect of gram-positive bacterium-induced sepsis on BBB permeability was also examined. As shown in Fig. 3, the BBB permeability was also increased after injection of *S. pneumoniae*, but with different kinetics from that of *E. coli*. The M4 tracers were not detected until 9 h after *S. pneumoniae* injection, and maximal numbers of M4 cells were found at 12 h (Fig. 3). The quantification of increased BBB permeability in *S. pneumoniae* sepsis is shown in Fig. 4.

The increase of BBB permeability during *E. coli*-induced sepsis was validated by the horseradish

peroxidase leakage assay. Transmission electron microscopic examination of brain tissues revealed no change in tight junctions at 1 h after E. coli injection (Fig. 5b). However, exogenous horseradish peroxidase was found deposited along blood vessels at 3 h after injection, indicating that the microvascular vessels were leaky, and the astrocytes also showed a sign of slight activation as vacuoles in the cytoplasm (Fig. 5c). Thus, it was concluded that the BBB permeability could be increased transiently during sepsis.

**TNF-α-induced alteration of BBB permeability**

The factors involved in the increase of BBB permeability during E. coli- or S. pneumoniae-induced sepsis were examined. The distribution of TNF-α in brain was determined by immunohistochemical staining. TNF-α was stained on the meninges and venules from 1 h to 3 h after E. coli stimulation (Fig. 6b and f), and had decreased by 6 h (data not shown). TNF-α was also detected on the meninges and venules of mice inoculated with S. pneumoniae, but at a later stage (6–12 h after injection) (Fig. 6c and g). Moreover, the brain venules in the parenchyma of mice treated with recombinant TNF-α also showed TNF-α staining (Fig. 6d and h). Furthermore, the increase of BBB permeability in either E. coli- or S. pneumoniae-induced sepsis could be inhibited by administration of anti-TNF-α antibody (Fig. 7). The direct i.v. injection of recombinant TNF-α, but not IL-1β, induced the BBB opening at 3 h after injection in a dose-dependent manner (Fig. 8). These findings suggested that TNF-α was responsible for the alteration of BBB permeability.

**Rapid clearance of bacteria from blood in E. coli- and S. pneumoniae-induced sepsis**

Peritonally administered E. coli or S. pneumoniae induced transient BBB opening. The number of E. coli or S. pneumoniae in blood after injection was determined. The results showed that no viable cells were detected 6 h after i.p. injection of 1 × 10^8 E. coli cells. The clearance rate of S. pneumoniae in blood was slower than that for E. coli, and all cells were removed within 12 h (Table 1).

**Discussion**

The blood-brain barrier, by virtue of its selective permeability, plays an important role in the migration of inflammatory cells into the brain micro-environment. The brain microvascular endothelial cells display several unique features such as the presence of tight junctions, no formation of pinocytic vesicles, and wrapping by astrocytes that constitute part of the BBB [11–13]. The M4 tracer permitted not only detection of entry to the brain, but also quantification of the degree of increase in BBB permeability [17,18]. PBS treatment alone had no effect on BBB opening, but
E. coli treatment is probably due to differences in the kinetics of serum TNF-α production stimulated by gram-positive and gram-negative bacteria. In B6 mice, E. coli-induced serum TNF-α reached a peak at 1 h, whereas with S. pneumoniae the peak was reached at 9 h [9]. The peptidoglycan and teichoic acid components of gram-positive bacteria are poorer TNF-α stimulators than the lipopolysaccharide (LPS) of gram-negative bacteria [22].

The increase in BBB permeability depended primarily on the action of TNF-α on microvascular vessels. The transmission electron microscopic examination of brain tissues stained with horseradish peroxidase also indicated leakage of microvascular vessels during sepsis. Endothelial cells respond to stimuli with acute alterations in mediator generation and surface expression. Vascular cells are both targets and sources of cytokines. These soluble mediators serve to communicate with leukocytes as well as other tissues and organs. Principal mediators in the pathology of sepsis are TNF-α and IL-1, which are released in large amounts by monocytes, macrophages and other leukocytes in response to bacterial toxins [2, 4, 5, 7]. IL-1 and TNF-α induce production of several cytokines in endothelial cells, including various chemokines, colony-stimulating factor, IL-6, and IL-1 itself [23–25]. Endothelial cells respond to the cell wall of S. pneumoniae by TNF-α production [26], and TNF-α release by blood-derived infiltrating cells, but not endothelial cells, has also been reported in experimental pneumococcal meningitis [27]. An earlier study reported maximal production of serum TNF-α (7 ng/ml) in B6 mice at 1 h and 9 h after E. coli and S. pneumoniae injection, respectively [9]. Direct i.v. injection of recombinant TNF-α not only induced BBB opening, but the venules in brain could also be stained with anti-TNF antibody. Endothelial cells are reported to express type I and type II TNF receptors, and the signal is mediated predominantly through the type I receptor [28–30]. In the present study, either TNF type I or type II receptors were manifested on brain venules in E. coli-induced sepsis (unpublished observations). The binding of TNF-α on endothelial cells in sepsis was probably due to the cell wall of circulatory TNF-α via a TNF receptor, but TNF-α produced by the endothelial cell response to stimuli was not excluded. There are discordant reports on whether direct injection of recombinant IL-1 into brain can induce CSF leukocytosis [31–33]. Intracerebral injection of E. coli induced the expression of IL-1β in brain arteriole in an experimental meningitis mouse model [18], but IL-1β could not be detected after i.v. injection of E. coli (unpublished observations) nor did i.v. injection of recombinant IL-1β induce BBB breakdown. Although IL-1β will cause meningeal inflammation in synergy with TNF-α, we believe that TNF-α is the major cytokine that induces the breakdown of BBB in sepsis.

The pathophysiology of bacterial meningitis involves both gram-negative and gram-positive bacterial sepsis induced an increase in BBB permeability. The reason for the kinetics of S. pneumoniae-induced increased BBB permeability being 9 h later than that observed in...

the invasion and multiplication of bacteria in the subarachnoidal space of the CNS. The bacterium itself, or its degraded products, stimulates the production and release of pro-inflammatory mediators such as cyto- kines and prostaglandins by leucocytes, endothelial cells, astrocytes, microglial cells and other cells in the CNS, which subsequently lead to an increase in the permeability of the BBB. This would trigger transen-
Fig. 7. Inhibition of increased permeability of the BBB in *E. coli* or *S. pneumoniae*-induced sepsis by anti-TNF-α antibody. Groups of four B6 mice were inoculated i.p. with *E. coli* or *S. pneumoniae* 1 × 10⁷ cells/mouse and killed at 3 h (a) or 12 h (b), respectively, after injection. Rabbit anti-TNF-α antisera (a, 40 μg; b, 80 μg) was injected i.v. simultaneously. Normal rabbit serum was used as a control. The M4 tracers (2 × 10⁷ cells) were administered i.v. 2 min before the animal was killed. doethelial migration of neutrophils and leakage of plasma proteins that could further damage the brain [14, 34]. However, it is not clear how the bacteria first enter the brain from a peripheral site. The observation in the present study that the TNF-α produced in the bloodstream by leucocytes during sepsis induced the increase in BBB permeability suggests the possibility that the peripheral bacteria may gain an entry to invade the brain through the BBB opening induced by TNF-α. Because the bacteria did not replicate continuously in the blood, the BBB opening was transient. When more bacteria (1 × 10⁸ cells) were given, serum TNF-α was

maintained at a high level and the BBB opening was sustained continuously (unpublished observations). Once foreign bacteria replicate effectively in the blood, they may gain a niche in the subarachnoid space by TNF-α-induced BBB opening. They can then replicate and stimulate more cytokine production, further increase the permeability of BBB, and induce the infiltration of neutrophils that constitutes the vicious cycle of bacterial meningitis.
