MOLECULAR DIAGNOSTICS

Early identification of *Mycobacterium tuberculosis* complex in BACTEC cultures by ligase chain reaction

S. X. WANG and L. TAY

Central Tuberculosis Laboratory, Department of Pathology, Singapore General Hospital, Republic of Singapore

A total of 1431 acid-fast bacilli (AFB) in Bactec® culture vials from 1427 patients was differentiated by the Bactec NAP® method and tested by the LCx *Mycobacterium tuberculosis* ligase chain reaction system. In all, 1321 of 1325 *M. tuberculosis* complex (MTBC) isolates were correctly detected by the LCx assay. All the 106 non-tuberculous mycobacteria (NTM) isolates were negative by the LCx assay. No false MTBC-positive result was obtained from NTM isolates. However, the LCx assay failed to detect four MTBC isolates from one patient. Sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were 99.7, 100%, 100% and 96.4%, respectively. These data suggest that the LCx system can be used to identify MTBC in AFB-positive Bactec broth cultures when the growth index is \(>100\). The method gives a 100% PPV and allows a faster turnaround time for MTBC than the NAP test.

Introduction

Rapid diagnosis of tuberculosis is an important component of measures to control the disease [1], which is an objective made more urgent by the appearance of multidrug-resistant strains [2]. Nucleic acid amplification techniques, which allow detection of *Mycobacterium tuberculosis* complex (MTBC) organisms directly from samples in a matter of hours, apparently represent the current best answer to this issue. However, the relatively low sensitivity of these techniques for smear-negative specimens restricts their use to selected sample types, primarily respiratory samples. Culture confirmation remains essential, as nucleic acid amplification techniques are unable to differentiate live from dead mycobacteria. The Bactec® radiometric method (Becton Dickinson, Towson, MD, USA) is one of the fastest and most sensitive cultural tools for the diagnosis of mycobacterial infections [3, 4]. The sensitivity of the radiometric assay allows a culture to reach a positive threshold in a very short time, often within 1–2 weeks. Confirmation of the presence of acid-fast bacilli (AFB) in a positive Bactec vial can be achieved by microscopy. However, a microscopically confirmed positive culture may be either MTBC or a non-tuberculous mycobacterium (NTM), which poses a dilemma both for therapy and for the measures to be adopted to prevent the spread of infection. Furthermore, differentiation of MTBC from NTM by the NAP (\(\rho\)-nitro-\(\alpha\)-acetamidinohydroxypropiophenet) test requires 4–8 days to give a result. A procedure enabling early identification of MTBC in a positive Bactec culture vial would be valuable.

This study investigated the reliability of a commercial ligase chain reaction system (LCx *M. tuberculosis*; Abbott Diagnostic Division, Abbott Park, IL, USA) [5, 6] for the detection of MTBC in AFB-positive Bactec culture vials.

Materials and methods

Bactec 12B® cultures showing a minimum growth index (GI) of \(>50\) were selected initially for inclusion in the study. An AFB smear was performed and, if positive, a NAP test was performed by standard methods [7]. For those vials in which no AFB were seen and for the LCx procedure, incubation was continued for at least 1 more day to produce a GI of \(>100\) with a positive AFB smear. In practice, GIs of cultures used in this study ranged from 100 to 999. Each broth culture that was differentiated as NTM by NAP was subcultured on solid medium and the mycobacterial species was identified by conventional
biochemical tests and commercial DNA probes (AccuProbe, San Diego, CA, USA). A total of 1431 Bactec 12B broth cultures from 1427 patients with GI of >100 was subjected to the LCx assay following the procedure recommended by the manufacturer for clinical samples. Briefly, 500 μl of each Bactec broth were transferred to a screw-capped microcentrifuge tube containing respiratory specimen buffer. The tube was vortex mixed and centrifuged (1500 g for 10 min) and the resulting pellet was washed and resuspended in buffer. After inactivation at 95°C for 20 min, the suspension was cooled to room temperature and lysed for 10 min in an Abbott Lysor sonicator. After further centrifugation (9000 g for 2 min), 100 μl of supernate were transferred to a tube containing the amplification mixture. Amplification was performed in a thermal cycler (LCx Thermal Cycler) for 37 cycles as follows: 94°C for 1 s, 64°C for 1 s, and 69°C for 40 s with maintenance at 25°C at the end of the last cycle. For each series of tests, the negative control and calibrator provided were prepared in duplicate and subjected to the same amplification procedure as the samples. Amplified tubes were pulse-centrifuged (10–15 s) and transferred unopened to the carousel of the LCx analyser, which directly detects amplification products by a microparticle enzyme immunoassay, reporting the results as fluorescence rates that are compared to the calibrator rate. Results >30% of the average of the calibrator rate were considered positive.

Results and discussion

Of the 1321 cultures that were positive for MTBC by the LCx assay, 1320 were identified as MTBC by NAP. The remaining sample proved to be a mixture of MTBC and M. kansasi. Of 110 mycobacterial cultures negative for MTBC by the LCx assay, 106 were identified as NTM by NAP (22 M. avium, 21 M. kansasi, 10 M. gordonae, 9 M. chelonae species group, 6 M. marinum, 5 M. fortuitum species group, 2 M. haemophilum and 31 other NTMs). The four MTBC isolates found to be LCx-negative were subcultured on solid medium and confirmed as MTBC by conventional biochemical tests plus commercial MTBC DNA probe. These four MTBC isolates were from samples from a single patient. No false-positive results were obtained. Sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were, therefore, 99.7%, 100%, 100% and 96.4%, respectively.

Several previous studies have evaluated the possibility of rapid detection of MTBC in early-positive Bactec vials. In the majority of these, the commercial AccuProbe was used [8–10]; the reported sensitivities ranged from 33% to 83%. In only one study were nine of nine positive cultures detected [11]. A commercial amplification assay (Amplicor MTB; Roche Molecular Systems, Somerville, NJ, USA) has also been investigated for the same purpose; the sensitivities obtained ranged from 66% to 100% [12–14]. In one study, an in-house PCR achieved better sensitivity and specificity results than a commercially available PCR product [14]. However, such procedures are only suitable for specialised laboratories, as they require dedicated personnel and facilities. The manufacturer does not recommend the use of the LCx system for the detection of MTBC from positive Bactec culture vials. However, the results of this study have shown that there is a good correlation between NAP and LCx results. The four isolates from a single patient that gave false-negative LCx results could be due to gene mutation or deletion of the LCx target nucleic acid sequence [15, 16]. These data suggest that the LCx system can be used to identify MTBC in AFB-positive Bactec broth cultures when the GI is >100. The method gives a 100% PPV and allows a faster turnaround time for MTBC than the NAP test.

We thank Ms Hla Hla Htay and Ha Kee Mong for their technical assistance.
