**INTRODUCTION**

*Clostridium difficile* is a well-established nosocomial pathogen, responsible for a significant number of cases of antibiotic-associated diarrhoea. *C. difficile*-associated diarrhoea is predominately a disease of the elderly who have undergone antibiotic treatment. It leads to increased patient morbidity, may contribute to mortality and is often associated with increased hospital stays.

It is well recognized that individual patients can carry this organism without any symptoms of disease. In healthy adults, the rate of asymptomatic colonization is thought to be less than 5% (Ambrose et al., 1985; Aronsson et al., 1985; Phillips & Rogers, 1981). However, several studies have shown that rates in hospitalized elderly patients may be much higher (Bender et al., 1986; Brazier et al., 1999).

The effects of antibiotic use on the gut flora are accepted as the major predisposing factor for the disease; however, there are likely to be many other influential risk factors for the infection.

Many different phenotypic and genotypic methods have been used to fingerprint strains of *C. difficile* in epidemiological studies (Brazier, 2001). The main aims of this investigation were to determine the level of *C. difficile* colonization and disease in a population of elderly patients and to investigate the association between strains in the patients and their environment. Three hundred and ninety patients between 62 and 101 years of age admitted to a geriatric unit in the Royal Victoria Hospital (RVH), Edinburgh, were investigated for the presence of *C. difficile*. *C. difficile* was cultured from 100 (26%) patients using pre-reduced cycloserine-cefoxitin egg yolk agar, and toxin(s) was detected in the faeces of 34 of these patients using the Techlab ELISA test kit for the detection of *C. difficile* toxins A and/or B. Toxin(s) was detected in a further 18 patients from whom no *C. difficile* was detected in culture. Of the patients in whom *C. difficile* was detected, 49% had diarrhoea, with the highest proportion of patients with diarrhoea being both culture- and toxin-positive for *C. difficile*.

Environmental sampling of the patient environment yielded *C. difficile* from 14% of samples. The organism was most frequently isolated from floors, sluice-rooms and toilet areas. The variation in the molecular mass of the *C. difficile* S-layer proteins was exploited as the basis of a novel typing method for *C. difficile*. Isolates from patients in the RVH were given a four-digit ‘S-type’ number based on their S-layer protein profile. A total of seven S-types were identified, with one type, toxigenic S-type 5236, accounting for 73% of all clinical isolates and 91% of environmental isolates.

**Abbreviations:** CDAD, *Clostridium difficile*-associated disease; RVH, Royal Victoria Hospital.
METHODS

Subjects. During the 17-month period July 1999 to December 2000, 865 geriatric patients were admitted to two wards (designated A and B) of the Royal Victoria Hospital (RVH), Edinburgh. The aim was to collect faecal specimens from patients with informed consent from all patients admitted as soon as possible after admission, and further specimens were collected weekly. Patient information relating to age, antibiotic therapy and symptoms of diarrhoea was collected. C. difficile associated diarrhoea was judged clinically and defined as at least one episode of diarrhoea (more than three loose stools per day) within the period of 2 weeks prior to and/or 2 weeks after a culture-positive stool was sampled. The ages of the patients from whom specimens were collected ranged from 62 to 101 years.

Faecal specimens. Faecal specimens were collected and investigated for the presence of C. difficile, irrespective of whether the patient had symptoms of diarrhoea. Fresh faecal specimens were transported to the laboratory as quickly as possible (during a working day) and investigated for the presence of C. difficile by culture and detection of toxins A and/or B directly in faecal samples.

Culture of C. difficile directly from faecal specimens. A standard loopful (approx. 0.2-2 g) of fresh faecal material was plated directly to pre-reduced cycloserine-cefoxitin egg yolk (CCYE) agar (Brazier, 1993). The cultures were incubated under anaerobic conditions (10% hydrogen, 10% CO2, 80% nitrogen) at 37 °C for 24–48 h and C. difficile was identified by Gram stain, characteristic smell, colonial morphology and chartreuse fluorescence under UV light (λ = 365 nm). Following subculture to blood agar, identity was confirmed by the above together with characteristic motility. Any atypical cultures were examined by gas chromatography for the characteristic volatile fatty acid products, including caproic and isocaproic acids (Poxton et al., 1996).

Detection of C. difficile directly in faecal samples by ELISA. Batches of faecal samples were tested retrospectively after storage at −20 °C for up to 60 days using the Techlab C. difficile TOX A/B ELISA test kit. The kit was used in accordance with the manufacturer’s instructions.

Toxin-producing potential of C. difficile isolates from patients in wards A and B, the RVH. Isolates of C. difficile were grown in brain heart infusion/proteose peptone medium (Mettler et al., 1982) at 37 °C under anaerobic conditions for 5 days for the detection of toxin. The Techlab C. difficile toxin A/B ELISA test kit was used to detect toxin(s) from pure C. difficile cultures.

Isolation and identification of C. difficile from the environment of wards A and B, the RVH. Inanimate surfaces and objects in wards A and B were sampled for contamination with C. difficile. Many surfaces were sampled; these included floors, commodities, toilet seats and areas within the sluice-rooms. Where practicable, samples were collected using 55 mm contact plates (Bibby Sterilin) with pre-reduced CCYE agar (Brazier, 1993). After sampling, the plates were stored in an anaerobic atmosphere for transport to the laboratory and incubated at 37 °C for up to 5 days. Sterile plain cotton wool swabs (Greiner Labortecnik) were also used to sample inanimate surfaces, such as door handles, toilet handles and taps. The swabs were moistened in sterile distilled water before sampling. The swabs were transported to the laboratory where they were inoculated to 4 ml fastidious anaerobe broth supplemented with cholic acid sodium salt and Modified C. difficile Selective Supplement (Oxoid). The broth cultures were incubated at 37 °C for 5 days under anaerobic conditions. A total of 672 samples were taken from ward A: 331 areas were sampled with contact plates and 341 with swabs. From ward B, a total of 676 samples were taken: 344 areas were sampled with contact plates and 332 with swabs.

Typing of C. difficile isolates – ‘S-typing’. C. difficile isolates from patients in the RVH were typed using a novel phenotypic typing method. The method utilizes the high degree in variation of the molecular masses of the two C. difficile S-layer proteins. The S-layer proteins were extracted using 5 M guanidine hydrochloride and visualized on SDS-PAGE with Coomassie staining. Following visualization on SDS-PAGE, the molecular masses of the S-layer proteins were calculated using Phoretix gel analysis 1-D software. Mark 12 molecular mass standards (Invitrogen) were used as calibrations for the calculation of molecular masses. Each isolate was given a four-digit number based on the molecular mass in kDa of the two S-layer proteins as described by McCoubrey & Poxton (2001). This typing method is known as ‘S-typing’.

Statistical analysis. All statistical analyses (chi-squared test, Mann–Whitney U test and logistic regression modelling) were carried out using SPSS software.

RESULTS

Detection of C. difficile by culture and detection of C. difficile toxins A and B

A total of 1003 specimens were obtained with informed consent from 390 (45%) of the 865 patients admitted to the geriatric unit. C. difficile was detected by culture from 206 (20%) of the 1003 specimens. These 206 specimens came from 100 (26%) patients. Toxins A and/or B were detected in 52 (13%) of the 390 patients. Of these 52 patients, 18 tested positive for toxin only and the remaining 34 patients were also positive by culture for C. difficile. These findings for the two different wards are summarized in Table 1, and show that C. difficile was detected in a total of 118 (30%) of the 390 patients investigated. Of these 390 patients, 17% were positive by culture only, 9% were positive by both culture and toxin tests, and toxin only was detected in 5% of patients.

When the results for wards A and B were compared, the overall level of detection of C. difficile by culture and/or toxin from patients in wards A and B was 58 (27%) and 60 (34%), respectively. The level of detection of C. difficile was not significantly different between the two wards (χ² test, P = 0.14).

Only 41% of patients who tested negative for C. difficile had been exposed to antibiotics, compared to 67% of patients from whom C. difficile was detected (Odds ratio 2.52; 95% confidence interval 1.60–4.16). Patients who tested positive for C. difficile toxin(s) were significantly older than those who were negative for toxin(s) (mean age 85.3 versus 82.2, P = 0.001).

Incidence of diarrhoea in patients who tested positive for C. difficile

Of the patients from whom C. difficile was detected, 49% had diarrhoea, compared to 39% without any evidence of C.
difficile. Seventy-nine per cent of patients who were culture- and toxin-positive had diarrhoea compared to less than a third of the patients who tested positive by culture only. We have defined Clostridium difficile-associated disease (CDAD) as symptomatic patients from whom both C. difficile and its associated toxin(s) were detected. From this definition, 4% (8/213) of patients from ward A and 11% (19/177) from ward B were determined as suffering from CDAD. However, up to a further 7% (15 patients) from ward A and 9% (15 patients) from ward B with diarrhoea may have been suffering from C. difficile-related symptoms as they harboured the organism but toxin was not detected. No other enteric pathogen was isolated from any patient during the study.

S-typing of C. difficile isolates from patients in wards A and B, the RVH

A total of 206 isolates from 100 patients in the RVH were subjected to S-typing and each isolate was given an S-type number. A total of seven distinct S-types were identified within the collection of isolates from patients in wards A and B. Three isolates from a single patient produced an atypical pattern with only one major S-layer protein—which was deemed untypable (UT). In addition to the SDS-PAGE analysis of the S-layer protein profiles, the C. difficile isolates were tested for their ability to produce C. difficile toxin(s) in culture by the use of the Techlab ELISA test kit for toxins A and/or B. This revealed that within S-type 5236, some isolates produced toxin(s) and other isolates did not. This allowed further differentiation within S-type 5236, therefore a total of eight different S/toxin-types were identified, with a further toxigenic UT strain. The S-layer protein profiles from representative isolates of each of the seven S-types identified and the UT strain are shown in Fig. 1. Details of the S-type, the toxigenic potential and the frequency of isolation are summarized in Table 2.

Toxigenic S-type 5236 was isolated from 78% patients and accounted for 150 of the 206 isolates from patients in the RVH. It was evident from the data that toxin-producing S-type 5236 was the endemic strain of C. difficile colonizing the wards. Each bay had its own designated toilet area and side-rooms. Each ward had five main bays with six beds in each, and each ward had five side-rooms. The wards were mirror images of each other and consisted of four main bays with six beds in each, and each ward had five side-rooms. Each bay had its own designated toilet area and

*One hundred patients in study. Total percentage is more than 100 as 14 patients were colonized with more than one S-type of C. difficile.

†This toxigenic strain did not produce the two distinct S-proteins on SDS-PAGE, thus an S-type number was not designated.

Patients in wards A and B, the RVH. The other S-types were isolated infrequently and were associated with very small numbers of patients.

Incidence of C. difficile in the environment of patients in wards A and B, the RVH

The wards were mirror images of each other and consisted of four main bays with six beds in each, and each ward had five side-rooms. Each bay had its own designated toilet area and

http://jmm.sgmjournals.org
the bathroom and shower-room facilities were shared between bays. Each of the side-rooms had its own designated toilet and bathroom facilities. In addition, each ward had a sluice-room and kitchen. *C. difficile* was isolated from 23% of samples taken by contact plates and 4% of samples using swabs.

The number of samples taken and the number of areas that tested positive from each room in wards A and B are summarized in Table 3. In ward A, *C. difficile* was most frequently isolated from the sluice-room, followed by the toilet areas associated with side-rooms. In ward B, the most frequent isolations were from toilet areas associated with side-rooms and the sluice-rooms themselves. The main toilet areas and sluice-room in ward B also had relatively high isolation levels, 17% and 15% of areas, respectively. The data in Table 3 show an overall level of isolation of *C. difficile* from the environment of ward A at 7% and from ward B at 20%. Correspondingly, all rooms of ward B showed higher levels of isolation of *C. difficile* than the equivalent rooms in ward A. Consistent with the overall results for wards A and B, the level of isolation of *C. difficile* in the side-rooms of ward B was much higher than those isolation levels from the side-rooms of ward A.

Of the areas sampled, *C. difficile* was most frequently isolated from floors; 29% of all floors from which samples were taken throughout wards A and B yielded a positive culture of *C. difficile*. Of the floors sampled, the toilet floors and the sluice-room floor yielded the highest isolation levels, with 40% of samples taken from toilet floors and 60% of samples from sluice-room floors yielding a positive result. Other areas with relatively high isolation levels included toilet seats (17%), commodes (11%) and toilet handles (8%), and three of the five toilet cisterns tested from ward B gave culture-positive results for *C. difficile*. Numerous other objects were sampled and gave positive results; amongst these, the paper-towel dispensers from the ward B kitchen, side-room 8 in ward B and bay 3 in ward B all tested positive for *C. difficile*. Two of six windowsills in ward B produced positive results, as did 25% of the shelves and cupboard tops from the sluice-rooms and bathrooms of ward B.

A total of 203 environmental isolates from 168 areas sampled were S-typed. All isolates tested were identified as belonging to one of the three major S-types 5236 (91%), 5242 (7%) and 5438 (2%). Most of these isolates were tested for toxin production and all were positive. Isolation rates of S-types 5236 and 5242 from the environment were plotted against isolation rates of these types from patients for each ward. The relationships were very complex (data not shown). In one ward (A) where there were peaks and troughs of isolations from both patients and environment, peak isolation rates from the environment seemed to precede peak levels in the patient. However, in the other ward, the relationships were not so obvious. Here the levels in the patients were much more constant but with peaks of isolations from the environment, possibly reflecting cleaning levels; however, this parameter was not measured quantitatively.

### DISCUSSION

This study of a geriatric unit investigated patients for colonization and infection with *C. difficile*, and revealed a 30% incidence of colonization with *C. difficile* in the patients investigated. Reported levels of isolation of *C. difficile* from different groups of hospitalized patients are highly variable. In close agreement with this study, McFarland et al. (1989) reported the isolation of *C. difficile* from 26% of patients in a general medical ward, and Gerding et al. (1986) reported that in a group of geriatric patients with diarrhoea, 30% harboured the organism. In an investigation of six different Welsh hospitals, 16.5% elderly patients acquired *C. difficile* during their hospital stay. Two of the Welsh hospitals investigated reported that *C. difficile* was not isolated and the range of acquisition by patients in the other four hospitals was 4–24% (Brazier et al., 1999). In a chronic care facility for elderly patients, 19.4% of the patients investigated were colonized, 9.8% were infected and 3.6% were colonized and infected (Hearn et al., 1992). The overall 30% colonization rate in our study was similar to these other reports.

</table>
the elderly, approximately 30 % of patients were found to harbour *C. difficile*. Of the patients studied, 28 % were toxin-positive and 33 % were culture-positive (Bender *et al.*, 1986). This compares well with the 27 % of culture-positive and 14 % of toxin-positive patients in the RVH. It also correlates with the overall detection level of 30 % from patients in the RVH.

Toxin was not detected in the faecal samples of 54 % of patients who were colonized with *C. difficile*. It is well recognized that toxin is often not present in the faeces of asymptomatic, colonized patients. This may be because the toxin is not produced in these patients in detectable quantities, or that patients are colonized by non-toxigenic strains.

From our study, 4 % of patients from ward A and 11 % from ward B were determined as suffering from CDAD. There were, however, a significant number of symptomatic patients from whom *C. difficile* was detected by culture or toxin testing, and although they did not fulfil the criteria for CDAD, their symptoms may be related to infection with *C. difficile*.

Sampling of the environment of the wards in the RVH indicated that ward B was much more heavily contaminated than ward A. *C. difficile* was isolated from 7 % of environmental surfaces sampled in ward A and 20 % of those surfaces sampled in ward B. These findings compare with a study which isolated *C. difficile* from 15 % of environmental surfaces in a chronic care ward for the elderly (Bender *et al.*, 1986) and an investigation by Al Saif & Brazier (1996) which isolated *C. difficile* from 20 % of inanimate objects from various hospital environments.

The areas with the highest isolation levels of *C. difficile* were toilet areas, sluice-rooms and side-rooms. As toilet areas and sluice-rooms are most likely to become contaminated by faecal material infected with *C. difficile*, this finding is not surprising. Patients who were symptomatic carriers of the organism often occupied the side-rooms and therefore contamination of such an environment is inevitable. McFarland *et al.* (1989) isolated *C. difficile* from 36 % of floors, 18 % of toilets and 38 % of commodes, and Samore *et al.* (1996) also isolated the organism from 48 % of floors, 41 % of commodes and 33 % of toilets. *C. difficile* was most frequently isolated from the floor of the RVH, and toilets and commodes were also frequently contaminated. The high levels of contamination of floors may be due to the initial contamination and subsequent movement of spores from place to place on the feet of staff, patients and visitors. Interestingly, McFarland *et al.* (1989) and Samore *et al.* (1996) isolated *C. difficile* from windowsills at levels of 30 % and 38 %, respectively. *C. difficile* was isolated from 20 % of windowsills sampled in the RVH. The organism was also isolated from shelves and cupboard tops. Areas such as these collect dust and may not be subject to cleaning as frequently as other areas, hence the spores collect and provide a reservoir of the organism. Fekety *et al.* (1981) reported the recovery of *C. difficile* from an intentionally contaminated surface for up to 5 months, demonstrating the ability of the organism to survive.

Environmental sampling of the study area utilized both contact plates and swabs. Samples taken by contact plates yielded a much higher isolation level of *C. difficile* than the samples taken with swabs. In a study comparing the relative merits of contact plates and swab methods, it was stated that contact plates were the preferred method of sampling and that they were better than swabs (Buggy *et al.*, 1983). It is therefore probably the case that the lower yields from the swabs were a result of the sampling method rather than the areas sampled.

**S-typing** is extremely simple to perform and comparison of isolates is exceptionally easy by the simple 2-band pattern produced. It was developed from one of the earliest and well-proven phenotyping methods, EDTA-extracted proteins, which has been performed extensively throughout the world. S-typing has been compared with PCR ribotyping and there was excellent correlation between the two methods (McCoubrey, 2002). A combination of S-typing and toxin testing of isolates from patients and the environment of wards A and B of the RVH identified a total of eight distinct S/toxin-types (with one untypable) from the 206 patient and 203 environmental isolates tested during the study. The endemic strain, toxigenic S-type 5236, colonized three-quarters of all the patients from whom *C. difficile* was isolated. This endemic S-type corresponded to PCR ribotype 1 (McCoubrey, 2002), which is the endemic strain in the rest of the UK (Brazier *et al.*, 1997). The seven other S/toxin-types and the untypable colonized a comparatively small number of patients. These findings were similar to those from a study carried out by Fawley & Wilcox (2001). Their study investigated the patients and the environment of two elderly general medicine wards over a 22-month period.

The toxigenic S-type 5236 that was endemic in patients in the RVH also accounted for the majority of the RVH environmental isolates. Two of the other eight S/toxin-types (5242/T and 5438/T) that were isolated from patients were also isolated from the environment, suggesting a possible association between the S-types isolated from patients and their environment.

Other studies have made associations between the contamination of the environment with specific strains and colonization of patients with the same strains. Cohen *et al.* (2000) showed that the AP-PCR types identified from patients in a geriatric and general medicine unit correlated closely with the types identified from the environment of these patients.

Interestingly, S-type 5438 was isolated from two patients in ward A and then several months later from three patients in ward B. All the patients colonized with this strain were housed in different bays, suggesting that contamination of the environment may not have been directly responsible if cross-infection occurred with this strain. In the study by Fawley & Wilcox (2001), they reported that a particular...
genotype was not isolated from the environment until the sixth patient in a cluster of cases became symptomatic. Data from both the RVH and Fawley & Wilcox (2001) suggest that an increase in the number of colonized patients can lead to an increase in the levels of environmental contamination with the colonizing strain. Fawley & Wilcox (2001) also suggested that initial cross-infection from patient to patient or from staff to patient may occur before heavy environmental contamination occurs and causes further cross-contamination. This may perhaps explain the transfer of S-type 5438 between patients in different bays within ward A. However, other sources such as commodes and equipment that are shared between bays within wards may be the common source of infection.

Due to the endemic nature of S-type 5236 in both the environment and the patients, it was not possible to determine whether environmental contamination or patient–patient and staff–patient spread was the main source of cross-infection in wards A and B, the RVH. Fawley & Wilcox (2001) encountered similar difficulties in determining the source of infection. They identified six different genotypes from the environment; however, only two of these were also isolated from patients and the endemic genotype corresponding to PCR ribotype 1 accounted for 92% of the environmental C. difficile isolates.

With the aid of a novel typing technique this study illustrates the endemic nature of C. difficile in a geriatric population and the degree to which their environment is contaminated. Much epidemiological evidence for the role of environmental contamination in the transfer of infection has been demonstrated; however, the relative importance of environmental contamination, patient–patient and staff–patient cross-contamination has to be determined. This stresses the paramount importance of infection control, including good hand-washing procedures by all health workers. It emphasizes the need for good ward cleansing practices at all times in order to reduce the opportunity for cross-contamination and the requirement for an effective disinfectant against C. difficile spores.

ACKNOWLEDGEMENTS

The authors would like to thank the Scottish Executive Chief Scientist Office (Grant No. K/OPR/22/D343) for supporting this research. We are grateful to Mr Robert Brown for his technical advice and to the nursing staff of the Royal Victoria Hospital for their cooperation during the study.
