Introduction

Zygomycosis, an opportunistic invasive infection caused by fungi of the class Zygomycetes, specifically orders Mucorales and Entomophthorales, is an uncommon disease, mainly confined to patients with haematological malignancy, organ transplantation, uncontrolled diabetes mellitus or other circumstances resulting in immunosuppression (Ribes et al., 2000; Walsh et al., 2004). Although the frequency of zygomycosis has been increasing over the past 10 years, there are only a few reports of this infection in immunocompetent patients. We report a fatal case of zygomycosis due to Rhizopus spp, causing necrotizing fasciitis in a young, otherwise healthy, trauma patient with multiple bone fractures and soft tissue injuries.

Case report

A 25-year-old, previously healthy male farmer was transferred to our hospital after he had been crushed by an agricultural tractor, when it was overturned while working in the fields. The emergency department evaluation revealed multiple open fractures of the right thighbone and the tibia, right hand (supracondylar humerus and ulna fractures), first-degree burns and multiple lacerations, abrasions and contusions throughout his body, and a large open wound in the right thigh. All wounds were contaminated with soil and organic material. Head and chest radiological examinations, including computed tomography (CT) scans, were normal. Stabilization of bone fractures was performed in an emergency surgery, followed by wound debridement.

Postoperatively the patient was admitted to the intensive care unit and was mechanically ventilated, he was haemodynamically stable, and sedated with 2–4 mg propofol kg⁻¹ h⁻¹ and 0.1–0.5 µg remifentanil kg⁻¹ min⁻¹. Arterial blood gas analysis on a fraction of inspired O₂ (FiO₂) of 0.4 showed pO₂ 174 mmHg, pCO₂ 33 mmHg and pH 7.41. The main laboratory findings were: 9.6 g haemoglobin dl⁻¹, 5 5 0 0 white blood cells ml⁻¹, 100 000 platelets ml⁻¹, 27 786 U creatine kinase l⁻¹, 22 U glutamic oxaloacetic transaminase l⁻¹ and 25 U glutamic pyruvic transaminase l⁻¹. The patient received empirical antibiotic therapy, including 5.2 g ticarcillin/clavulanic acid every 8 h, 600 mg clindamycin every 6 h and 400 mg ciprofloxacin every 12 h. On day 3 in the intensive care unit a chest X-ray showed atelectasis of the right upper lobe (Fig. 1) and a marked hypoxemia was noted; pO₂ was 60 mmHg and pCO₂ 44 mmHg at FiO₂ 0.1. Atelectasis was resolved by fibre-optic bronchoscopy, which revealed purulent material in the corresponding bronchus. Culture of the bronchial washings, on Sabouraud dextrose agar, yielded fungus. Microscopic examination of growth, using lactophenol cotton blue, revealed the presence of nonseptate broad hyphae with nondichotomous, irregular branching, at right angles, and well developed rhizoids, indicative of Rhizopus spp. In addition, Candida spp. and a few colonies of Gram-negative bacteria were cultured. Liposomal amphotericin B (4 mg kg⁻¹ per day) was immediately started. However, the patient’s clinical...
condition gradually deteriorated with fever up to 39°C and hypoxemia. Chest X-ray and CT scan revealed the reappearance of atelectasis, bilateral pleural effusion and diffuse pulmonary infiltrates. A second bronchoscopy disclosed again purulent secretions and haemorrhagic mucosa with oedema in both main and subsegmental bronchi. Again, the bronchoalveolar lavage fluid culture revealed *Rhizopus* spp., *Aspergillus* spp. and Gram-negative bacteria. The dose of liposomal amphotericin B was increased to 8 mg kg\(^{-1}\) per day.

Additionally, at the same time compartment syndrome developed in the right leg, where the large open wound was, requiring fasciotomy (Fig. 2). Wound samples culture showed multiple pathogen growth, including *Rhizopus* spp., *Aspergillus* spp., *Enterococcus faecalis* and Gram-negative bacteria. Debridement was carried out once or twice daily. Despite the multiple surgical debridements and antibiotic treatment against the pathogens isolated, the wound gradually deteriorated. The wound margins turned violaceous, and the skin and subcutaneous tissue became necrotic. Histopathological examination of excised tissue specimens showed extensive necrosis and invasion of the vessels, and the presence of broad aseptate hyphae with right-angle branching, consistent with the morphology of *Zygomycetes* (Fig. 3). A human immunodeficiency test was negative. Despite the supportive care, surgical debridements, and antibiotic and antifungal treatment, the patient’s condition deteriorated, and he died from refractory septic shock on the 19th day post-trauma.

### Discussion

Zygomycosis typically occurs in patients with leukaemia, solid organ or bone marrow transplants, diabetes mellitus, neutropenia or who are undergoing treatment with steroids. *Zygomycetes*, especially *Mucorales*, are widespread in nature, subsisting on decaying vegetation and diverse organic materials. The most common route of transmission is inhalation of spores from the environment. For this reason rhinocerebral and pulmonary zygomycosis are the usual types of this infection in immunocompromised patients, followed by gastrointestinal, cutaneous and disseminated infection (Ribes et al., 2000; Walsh et al., 2004).

Although *Mucorales* show minimal intrinsic pathogenicity towards immunocompetent persons, they can initiate...
aggressive and fulminant infections under certain clinical conditions (Ribes et al., 2000; Walsh et al., 2004). Rhizopus, Mucor, Rhizomucor, Absidia and Apophysomyces are the most commonly encountered genera. In particular, cutaneous involvement was the presented pattern in 176/929 patients (19%) in a review of all English language reports of zygomycosis. Penetrating trauma was reported for 60/176 (34%) of these patients (Rodén et al., 2005). A direct entry of environmental fungi through superficial wounds at the time of the accident has been implicated.

The severity of cutaneous zygomycosis in otherwise healthy trauma patients with open wounds, ranges from contamination to extensive necrotizing fasciitis (Patino et al., 1991; Cocanour et al., 1992; Kordy et al., 2004; Tang & Wang, 1998; Adam et al., 1994; Johnson et al., 1987; Song et al., 1999; Andresen et al., 2005). Reported cases include 8 patients with severe necrotising fasciitis due to zygomycosis after a volcanic eruption in Colombia (Patino et al., 1991), a collective series of 11 trauma patients with cutaneous involvement of diverse severity (Cocanour et al., 1992) and other isolated reports. An additional case of zygomycosis, caused by Apophysomyces elegans, in a previously healthy patient, who developed necrotic and disseminated soft-tissue lesions after traumatic injury as a result of the tsunami that ravaged the Indian Ocean has been recently reported (Andresen et al., 2005).

Pulmonary mucormycosis is very rare in the absence of an underlying illness (Lee et al., 1999; Butala et al., 1995; van Dam et al., 2005). Isolated pulmonary mucormycosis, due to Rhizopus spp., in a previous healthy, young trauma patient with multiple injuries has been recently reported (Aboutanos et al., 2003). It was suggested that he became prone to this infection, since the protective role of the pulmonary macrophages and neutrophils were compromised in the setting of pulmonary contusion that he had. The patient in the present case did not have signs of lung contusion in the chest X-ray and the CT scan on admission. However, the contribution of the relative immunosuppression that the multiple trauma brings about, and the direct contamination of the wounds with soil rich in organic material, may explain in part the fungal infection.

Lung tissue biopsy is necessary for the definitive diagnosis of pulmonary zygomycosis. Such an intervention was not done in our patient; therefore, there is no direct evidence of the pulmonary fungal infection. However, it could be considered that our patient, as a farmer, may have already had the upper respiratory tract colonized by Rhizopus spp. before the accident. Since non-septate hyphae were found in both bronchial washings and bronchoalveolar lavage fluid cultures, fungal infection was highly likely.

In all mentioned studies of either cutaneous or pulmonary zygomycosis, the best outcome was obtained when the diagnosis was made early, aggressive surgical debridement was used and high doses of amphotericin B were given. Nonsurvivors usually had rapidly progressive infection, whereas survivors had minor disease. In our patient the disseminated severe infection probably contributed to his fatal outcome.

In conclusion, rapidly progressive zygomycosis can occur in otherwise healthy individuals following trauma. A high level of clinical suspicion is important in any trauma patient, especially in the presence of open wounds and soft tissue injuries contaminated with soil, even in the absence of immunosuppression. Early recognition is essential in order to control this uncommon infection by combined surgical and medical therapy.
