Many of the diseases peculiar to western civilisation have been ascribed to the removal from the diet of the major part of the fibre of the wheat grain. It has been suggested that this part of the wheat grain, known as bran, is of specific value in the prevention of various diseases including large bowel cancer (Burkitt, 1971). The prophylactic influence of bran is ascribed to its effects on intestinal transit, faecal bulk and the faecal flora. The effect of bran on intestinal transit and faecal bulk has been previously documented (Cowgill and Anderson, 1932; Harvey, Pomare and Heaton, 1973). In this paper we describe the effect of bran on the faecal flora.

MATERIALS AND METHODS

Plan of Study. Four healthy male medical students (nos. 1–4) aged 22–25 took part in the study. The protocol was fully explained to each subject and had been approved by the ethical committee of the Central Middlesex Hospital. For 6 weeks the subjects ate a carefully prepared metabolic diet whilst living in a hostel in the hospital grounds and carrying out their normal occupations.

The basic diet was a 2902 K cal. low-fibre diet of normal “western” composition comprising 351 g of carbohydrate, 122 g of fat and 88 g of protein, and it contained 3.6 g of crude fibre. This was fed for 3 weeks; for the other 3-week period the fibre content of the diet was increased (high fibre diet) by substituting an equal weight of wholemeal bread for the white bread (120 g), All-bran for cornflakes (25 g), bran biscuits for Nice biscuits (52 g), and by adding 30 g of bran (Allison’s Bran+). The high-fibre diet supplied 2775 K cal. as 339 g of carbohydrate, 115 g of fat and 97 g of protein, and it contained 11.7 g of crude fibre. Apart from the substitutions, the two diets were identical. Data were not available for the dietary-fibre (as opposed to crude-fibre) content of all the items, but this information was obtained for the four items changed in the two diets by the method of Southgate (1969). From this it was calculated that the high-fibre diet contained an additional 36 g of dietary fibre. Subjects nos. 1–2 took the low-fibre diet first and subjects nos. 3–4 the high-fibre diet first. Further details of the diets are given by Jenkins, Hill and Cummings (1975).

Throughout the 6-week period and for 1 further week the subjects collected their faeces. Each stool was collected separately into a plastic bag fixed over a toilet.

Mean transit time (MTT) was measured during the third week of each diet period by giving a single dose of 25 opaque pellets with breakfast and determining their presence in the collected stools radiographically.

Preservation of specimens. From a freshly passed stool, 0.5 g of faeces was mixed with 4.5 ml of glycerol broth 10% (v/v) in a 10-ml screw-capped bottle. The suspension was

placed in a container of solid carbon dioxide and was stored at -80°C. This procedure ensured that losses of bacteria are minimised (Crowther, 1971).

Culture of specimens. Serial dilutions of the specimens were prepared and plates of media for the isolation of anaerobic organisms were seeded within an anaerobic chamber. A flexible polyvinyl chamber filled with a mixture of 10% hydrogen in nitrogen was used (Aranki et al., 1969; Drasar, 1974).

To maintain the media in a reduced state, uninoculated plates were stored for 3 days in the anaerobic cabinet before use. The diluent was heated to 100°C before being introduced into the cabinet where it was dispensed and allowed to cool in the anaerobic environment. Plates seeded within the cabinet were packed into anaerobic jars and removed from the cabinet via the airlock. All anaerobic jars were evacuated and filled with a gas mixture containing CO2 30% and H2 70%. The atmosphere of the anaerobic jars was replaced twice. Cold "D" catalyst (Engelhard Industries, Cinderford, Gloucestershire) was used in the anaerobic jars.

Ten-fold dilutions of the specimen were prepared in Brain-Heart Infusion Broth (Oxoid) with the addition of cysteine hydrochloride 0-05% (w/v) and sodium formaldehydesulphoxalate 0-03% (w/v). Samples (0-1 ml) of appropriate dilutions were spread on the surface of the plates of the various selective and non-selective media used in previous studies (Drasar, 1967).

In addition to these media, Brain-Heart Infusion Agar (Oxoid) containing (w/v) Yeast Extract (Oxoid) 1%, cysteine hydrochloride 0-05% and sodium formaldehydesulphoxalate 0-03%, enriched with 10% defibrinated horse blood was used for the isolation of non-sporing anaerobic bacteria and this medium supplemented with 10% bile (Oxoid) and kanamycin sulphate 1000 μg per ml was used to ensure the selection of Bacteroides fragilis.

After incubation, the colonies growing on the various media were counted. Ten strains of non-sporing anaerobic bacteria and 10 strains of clostridia were sampled from each specimen. The non-sporing anaerobes were further identified as described previously (Peach et al., 1974). The volatile fatty acid end-products of glucose metabolism were detected with a Perkin-Elmer F.40 Automatic head-space analyser (Drasar et al., 1976).

The ability of the clostridia to dehydrogenate the steroid nucleus was tested with the improved method of Goddard et al. (1975).

Faecal glucuronidase assay. The amount of β-glucuronidase in faecal specimens was assayed as described by Reddy and Wynder (1973).

RESULTS

The addition of fibre to the diet produced no demonstrable change in the relative numbers of the groups of bacteria counted in the faeces; the results obtained during the final week of each of the test diets are compared in the table. However, the output of faeces was increased on the high-fibre diet from 74-5±14-3 g per day to 223±33-2 g per day (N = 4); the mean transit time fell significantly from 63-0 (+16-7) h to 38-8 (+7-7) h on this high-fibre diet. As judged by “Student’s” t test these differences were significant (t = 3-8, P<0-02). Thus, the total number of bacteria excreted daily increased about three-fold when a high-fibre diet was eaten.

The dominant bacteria

Non-sporing anaerobic bacteria were the predominant faecal organisms isolated from all the subjects examined, but the dominant species was different for each of the four subjects. Indeed, the combination of species isolated from the faeces was characteristic of each individual. Bact. fragilis, Bifidobacterium
Fig. 1.—Variations in relative proportions (expressed as percentages of total anaerobes) of the stated species of non-sporing anaerobic bacteria isolated from the faeces of subjects nos. 1 and 2 during change from low-fibre to high-fibre diet: •—• = Bacteroides fragilis; ○—○ = Bifidobacterium adolescentis; ▲—▲ = Peptococcus asaccharolyticus; △—△ = Eubacterium aerofaciens.
adolescentis and Eubacterium aerofaciens were isolated from specimens obtained from subjects nos. 1 and 2 during both dietary periods. Specimens from subject no. 4 yielded a greater proportion of Bact. fragilis than did specimens from the other subjects. Peptococcus asaccharolyticus was isolated from subject no. 1 only. Isolates obtained from specimens produced by subject no. 3 were almost all identified as Bi. adolescentis. The changes in the patterns of these isolations with time are presented in fig. 1 (subjects 1 and 2) and fig. 2 (subjects 3 and 4).

In addition to these organisms, one strain of Fusobacterium prausnitzii was isolated from each of subjects nos. 3 and 4; two strains of Eu. rectale were isolated from subject no. 1, and two strains of Pept. productus were isolated from subject no. 2. In all, 309 strains of non-sporing anaerobic bacteria were isolated; of these, 27 isolates were not identified.

Faecal β-glucuronidase

The concentration of faecal β-glucuronidase was assayed in two subjects; it was unaffected by the change in diet.

Clostridia able to dehydrogenate the steroid nucleus (NDC)

Clostridia with this biochemical activity (Goddard et al., 1975) were isolated from only one of the four subjects studied. Their concentration was not influenced by changes in diet. Indeed, the number of clostridia detected in all subjects varied little (the table). It should be noted that, as a result of the design of the study, the presence of NDC clostridia could have been masked by the presence of other clostridia unless the NDC clostridia exceeded 10% of the total.

DISCUSSION

Diet is thought to be one of the main factors controlling the intestinal flora (Dudgeon, 1926), but attempts to alter the flora of adult man by dietary changes have produced disappointing results. Only the feeding of low-residue liquid-formula diets has produced reproducible changes (Attebery, Sutter and Finegold, 1972; Crowther et al., 1973). However, alterations in the metabolic activity of the flora can be shown even when alterations in the bacterial genera and species making up the flora cannot always be detected by classical bacteriological procedures. Thus, the feeding of meat alters the levels of β-glucuronidase in faeces (Reddy, Weisburger and Wynder, 1974) although, at best, only minimal changes in the flora are detected (Maier et al., 1974).

Most components of the diet are absorbed very efficiently by the small intestine. Any influence of protein, fat and digestible carbohydrate will, therefore, be mediated by the host metabolism and may be a long-term process. On the other hand, it might be expected that any effect of substances, such as "fibre", that pass directly into the colon would be manifested quickly. The amount of fibre entering the large bowel is said to influence the flora and control the development of large-bowel cancer.
FIG. 2.—Variations in the relative proportions (expressed as percentages of total anaerobes) of the stated species of non-sporing anaerobic bacteria isolated from the faeces of subjects nos. 3 and 4 during change from high fibre to low fibre diet: •—• = Bact. fragilis; ○—○ = Bi. adolescentis.
Cancer of the colon and rectum occurs primarily in developed countries. The incidence is high in Western Europe and North America but low in Africa, Asia and most of South America and this is thought to be related to the bacterial production or activation of carcinogens in the intestine. In a previous study, in which the flora of faeces from populations in areas with low and high incidences of colon cancer, bacteroides organisms were shown to be more common in faeces from areas in which the incidence of cancer of the large bowel is high whereas eubacteria were more common in faeces from low-incidence regions (Peach et al., 1974). Bile salts are thought to provide the substrate for the production of carcinogens or co-carcinogens by bacteria. International comparisons have shown that the concentration of bile acids in faeces is higher in high-incidence areas than in low-incidence areas; moreover, the bile acids from high-incidence populations were subject to a greater degree of bacterial degradation (Hill et al., 1971). A pathway for the production of carcinogens from bile acids was postulated by Hill (1971), a key reaction in this scheme being the dehydrogenation of the steroid nucleus. This reaction is performed only by clostridia, notably Clostridium paraputruticum. These organisms are isolated more frequently from populations in high-incidence areas than from populations in areas of low incidence (Drasar et al., 1976). In addition, evidence of the probable significance of these clostridia has been provided by a retrospective study of cancer patients (Hill et al., 1975).

Burkitt (1971) suggested that the differences in the incidence of cancer

WHEAT FIBRE AND HUMAN FAECAL FLORA

of the large bowel resulted from the influence of the large amounts of dietary fibre consumed in low-incidence areas on the bacterial flora and physiology of the large bowel. The addition of bran to the diet of persons in high-incidence areas was suggested as a prophylactic measure. The relationship of fibre intake to the incidence of large-bowel cancer has been studied in several epidemiological investigations; no strong correlation can be demonstrated between a low incidence of large bowel cancer and fibre consumption (Irving and Drasar, 1973; Armstrong and Doll, 1975). This lack of correlation may be explained by the differences in the types of fibre consumed in various parts of the world; wheat bran is not consumed by people living in low-incidence areas.

In the present study, no effect of bran on the numbers and types of bacteria present in faeces could be demonstrated although an increase in the rate of intestinal transit was observed. As mentioned previously, when the flora of faeces from populations in low- and high-incidence areas was examined, differences were found in the proportion of the various groups of non-sporing anaerobic bacteria isolated (Peach et al., 1974). If these results are to be explained in terms of the intake of fibre it would be expected that a decrease in the numbers of bacteroides organisms and an increase in the numbers of eubacteria would be seen. Moreover, NDC clostridia would be expected to disappear under the influence of wheat fibre. No such effect was demonstrated. Although NDC clostridia can be reliably detected only when not masked by other organisms, a reduction in their number to less than 10% of the total would have been detected. Work on these organisms is hampered by the lack of a reliable selective system. No change in the level of β-glucuronidase in faeces was detected in the two subjects from whom samples were assayed.

The most notable observation made during the present study was that the dominant non-sporing anaerobic bacterial species found in the intestine seemed to be a characteristic of the subject examined. Previous studies have suggested this (see, for example, Moore and Holdeman, 1974); whilst Moore and Holdeman's study relates to the exhaustive study of single samples, our conclusion resulted from the examination of several samples from each subject. The singularity of the flora is well illustrated by our findings with subject no. 3 whose flora was dominated by *Bi. adolescentis*; even when this subject was consuming a high-fibre diet, *Bi. adolescentis* was never less than 80% of the non-sporing anaerobic bacteria isolated. Although some fluctuation in the relative proportions of the various non-sporing anaerobic bacteria was observed during this study, these changes could not be ascribed to the dietary changes; the differences between subjects were greater than those within subjects throughout the investigation.

When considering the factors that control the flora, the genetic constitution of the host should perhaps be considered. During studies of the inherited disease familial polyposis coli, it was shown that in patients with this condition the metabolism of cholesterol by the large bowel flora did not take place although the flora could perform this reaction in vitro (Bone, Drasar and Hill, 1975). It seems that the resistance of the flora to change despite major alterations of diet reflects the over-riding controlling role of host factors that are
yet to be defined. Our study indicates that a brief change of diet seems to have little effect on the remarkable homeostasis of the bowel.

**Summary**

The effect on the faecal flora of adding wheat fibre to a controlled diet in four healthy volunteers for a 3-week period has been observed. No change in the concentration of the bacteria in the bacterial groups counted was found, although there was a slight increase in total output associated with increased faecal weight. The predominant organisms in all subjects were non-sporing anaerobes, but the dominant species in each subject was different and was unaffected by changing the diet. Similarly, the concentration of faecal β-glucuronidase detected in two subjects was unaltered and the concentration of clostridia able to dehydrogenate the steroid nucleus found in one subject was unaltered.

It is suggested that the faecal microflora is not primarily controlled by the presence of undigested food residues in the large bowel.
