**Introduction:** *Clostridium difficile* infection (CDI) is a significant gastrointestinal disease in the developed world and increasingly recognised as a zoonotic infection. In North America and Europe, the PCR ribotype (RT) 078 strain of *C. difficile* is commonly found in production animals and as a cause of disease in humans although proof of transmission from animals is lacking. This strain is absent in Australian livestock. We report a case of human CDI caused by a strain of *C. difficile* belonging to known Australian livestock-associated RT 237.

**Case presentation:** A young male was admitted for multiple trauma following a motor vehicle accident and placed on piperacillin/tazobactam for pneumonia. After 4 days of treatment, he developed symptoms of CDI, which was confirmed in the laboratory. His symptoms resolved after 6 days of intravenous metronidazole. The strain of *C. difficile* isolated was identified as RT 237, an unusual RT previously found in several Western Australia piggeries.

**Conclusion:** This case of CDI caused by an unusual livestock-associated *C. difficile* RT 237 supports the hypothesis of zoonotic transmission. The case highlights the potential of livestock to act as reservoir for *C. difficile* and the need for continued surveillance of CDI in both human and animal populations.

**Keywords:** *Clostridium difficile* infection (CDI); zoonosis; diarrhoea; PCR ribotyping; antibiotics; metronidazole.

2016). This report describes the isolation and characterisation of a C. difficile RT 237 strain in a case of human infection, initially identified in a cross-sectional study of CDI epidemiology in WA (Foster et al., 2014).

**Case report**

A 19-year-old Caucasian male was admitted to Bunbury Regional Hospital (BRH) in WA during February 2012 for multiple trauma following a motor vehicle accident. The patient, a New Zealand national, was in Australia working as a dairy farmer. He had been hospitalised at BRH 3 months earlier for a crush injury of his hand. He had no known allergies and his only other medical history was of mild asthma requiring occasional inhaled salbutamol. He was transferred from BRH to the State Trauma Unit at Royal Perth Hospital via the Royal Flying Doctor Service.

Initial computerised tomography and X-ray scans revealed a minor mandibular fracture, two severe distal phalangeal fractures and extensive pelvic fracturing with associated haematoma. Haemoperitoneum and lacerations to the skin, right kidney and bladder were also found. On admission, the patient was placed on 4.5 g intravenous (IV) piperacillin/tazobactam three times daily for 6 days to prophylax against infection complicating the pelvic and abdominal trauma. Pelvic injuries were initially managed conservatively, but on the second day of his admission, after worsening abdominal pain, he underwent an exploratory laparotomy. At the procedure, a bladder injury was noted and repaired. On the same day, he also underwent surgical debridement of the finger wounds. Mandibular fractures were managed conservatively.

On the fourth day of admission, the patient developed a fever with a temperature of 38.4 °C and associated tachycardia and tachypnoea. He began to exhibit abdominal distension and frequent bowel motions with loose stools. Blood cultures taken at this time were negative. At 7 days post-admission, IV piperacillin/tazobactam was ceased. The patient underwent an open reduction and internal fixation of the pubic symphysis and was commenced on IV cephalaxin 2 g 8 hourly. After 6 days of metronidazole treatment (16 days post-admission), his fever and CDI symptoms had subsided. A faecal specimen collected 23 days post-admission was PCR negative for the toxin B gene and the patient was discharged to the physical rehabilitation unit after a total of 46 days as an in-patient. The patient completed 6 weeks of IV antimicrobial therapy for the infection of the pelvic plate, after which time he continued on oral cephalaxin, with the plan for this to continue until the pelvic plate could be definitively removed. No further episodes of CDI were noted.

**Investigations**

C. difficile was cultured from the PCR-positive stool specimen as previously described (Boseiwaqa et al., 2013); the strain isolated was designated WA 1016. PCR ribotyping and PCR detection of the genes encoding toxin A (tcdA), toxin B (tcdB) and the binary toxin (CDT) component genes (cdtA, cdtB) were performed as described previously (Knight et al., 2013). WA 1016 gave a PCR ribotyping pattern consistent with RT 237 (Fig. 1) and was positive for tcdB and both CDT genes but negative for tcdA (A B CDT), a toxin profile also consistent with C. difficile RT 237. Antimicrobial susceptibility testing was performed using the agar incorporation method as described by Clinical and Laboratory Standards Institute (CLSI) (CLSI, 2011; CLSI, 2013). All clinical breakpoints were provided by CLSI (CLSI, 2013) with the exception of those for vancomycin and rifaximin that were recommended by the European Committee on Antimicrobial Susceptibility Testing [EUCAST (2016) and O’Connor et al. (2008), respectively]. WA 1016 was resistant to trimethoprim but susceptible to vancomycin, metronidazole, rifaximin, clindamycin, erythromycin, moxifloxacin and piperacillin/tazobactam. The fidaxomicin minimum inhibitory concentration of WA 1016 was 0.008 mg l⁻¹ (no clinical breakpoints for fidaxomycin are currently available). The antimicrobial susceptibility profile of WA 1016 matched those typical of animal RT 237 isolates (Knight & Riley, 2016).
The epidemiology of CDI is complex and ever-changing, with recent evidence pointing to genetically diverse sources of infection (Eyre et al., 2013) and possible zoonotic transmission in Europe (Knetsch et al., 2014). The potential for zoonotic transmission of C. difficile in Australia has also been suggested (Knight et al., 2015b). In Australian livestock, the molecular epidemiology of C. difficile is different from that seen elsewhere in the world. The strain most commonly associated with production (food) animals in the global setting is RT 078 and this strain is not found in Australian livestock, although many related strains also belonging to phylogenetic clade 5 are present (Knight et al., 2013). In Australian piglets, RTs 014 and 033 were the most common RTs recovered, followed by RTs 281 and 257 (Knight et al., 2015c). In Australian veal calves slaughtered at 5–7 days old, the most frequently encountered RTs were RTs 127 and 033 followed by RTs 056 and 126 (Knight et al., 2013). C. difficile RT 237 was absent in veal calves (Knight et al., 2013). Crossover between animal and human RTs of C. difficile in Australia appears to be occurring with RTs 014 and 056 being common RTs found in both humans and animals (Foster et al., 2014); however, this needs to be confirmed with whole genome sequencing. The high prevalence of RT 033 in livestock does not seem to be mirrored in humans; however, the absence of toxin A and B production in this strain may preclude its detection in many diagnostic laboratories (Androga et al., 2015).

C. difficile RT 237 belongs to toxinoype XXXI and is missing a large portion of the 5’ end of the tcdA gene yet retains an intact tcdB gene (Rupnik & Janezic, 2016). Certain diagnostics tests reliant on detection of the missing fragment of tcdA, such as the Illumigene® C. difficile test (Meridian Bioscience), will also not detect RT 237 (Androga et al., 2015). Diagnostic issues such as these are compounded by recent trends away from culture and greater reliance on molecular tests (Burnham & Carroll, 2013). C. difficile RT 237 is an unusual ribotype rarely seen as a cause of disease in humans in Australia. This is in marked contrast with RT 078, which is commonly detected in both humans and animals outside Australia (Goo rhuis et al., 2008). Interestingly, RT 078 infections in Australian patients still occur (Knight et al., 2015a) in the absence of overseas travel suggesting another reservoir of infection, perhaps imported food. Since routine surveillance began in WA in 2011, only six other cases of human CDI involving RT 237 have been recorded (TV Riley et al., unpublished data). However, C. difficile RT 237 has been isolated from WA piggeries for many years and remains highly prevalent (Moono et al., 2016; Squire et al., 2013). To our knowledge, RT 237 has not been reported elsewhere in the world and was not mentioned in a recent publication describing strains of C. difficile isolated from animal populations around the world (Janezic et al., 2014). To what extent that the lack of C. difficile RT 237 infections described in other parts of the world is due to detection issues remains unclear.

The source of infection in our case is difficult to determine. As symptoms began after 48 h of admission to a healthcare facility, the case was classified as hospital-associated healthcare facility onset according to McDonald et al. (2007). No cases of RT 237 had occurred at BRH prior to the patient’s admission. The apparently exclusive distribution of C. difficile RT 237 in production animals in WA (Knight et al., 2015c; Moono et al., 2016; Squire et al., 2013) is suggestive of transmission within the state. The patient lived in shared accommodation in a rural area working as a dairy farmer. RT 237 was not isolated from dairy (veal) calves in a previous Australian surveillance study (Knight et al., 2013); however, this study did not include WA calves. C. difficile RT 237 has been isolated from several piggeries in WA and there is pig rearing in the region of WA where the patient lived. Comprehensive surveillance of C. difficile in livestock is not in place nor is it likely to be in the near future, making it difficult to get a complete picture of the distribution of this ribotype. We recently isolated C. difficile RT 237 from vegetables sold in several grocery stores in WA (Lim, Foster & Riley., unpublished data). This suggests contamination of vegetables by piggery effluent. Possible food-borne transmission of another clade 5 strain, RT 126, common in Australian cattle, has recently been reported (Knight et al., 2015b).
potential of contaminated food as a route of transmission of *C. difficile* has been gaining more attention (Gould & Limbagho, 2010; Rupnik, 2007; Weese, 2010). Additionally, the role of the broader environment as a reservoir for *C. difficile* requires further investigation. There are difficulties in studying transmission of *C. difficile* outside the hospital; however, data from the limited number of surveys performed so far suggest that *C. difficile* is present widely in soil and water (Al Saif & Brazier, 1996).

This report demonstrates that *C. difficile* RT 237, an animal strain of *C. difficile* reported only in WA, can be associated with human infection. This finding supports our previous observation that *C. difficile* RT 237 caused significantly greater weight loss in mice than *C. difficile* RT 078 due to the production of a variant toxin (Squire et al., 2013) and highlights the potential risk that animals carrying this strain may pose to humans. Surveillance of animal populations is needed to clarify the relationship between livestock-associated *C. difficile* and human CDI. Ultimately, the promotion of a dialogue between physicians, veterinarians and scientists in the development of a One Health approach will be essential to control CDI.
