The Effect of Ethidium Bromide Mutagenesis on Dimorphism, Extracellular Metabolism and Cytochrome Levels in *Aureobasidium pullulans*

By PATRICK J. KELLY* AND BRIAN J. CATLEY

(Received 7 February 1977; revised 3 May 1977)

Treatment of the dimorphic fungus *Aureobasidium pullulans* with ethidium bromide resulted in the production of several mutants, cultures of which produce an increased proportion of yeast-like cells. A comparison of several mutant isolates with the wild type suggested that the yeast-like cell is responsible for the production of the polysaccharide, pullulan. Mutation was also shown to affect other metabolic patterns, e.g. the reduced accumulation of extracellular ethanol by the mutant. The cytochrome components of the respiratory chain in the wild type were examined by whole-cell spectrophotometry and compared with those of the mutants; the latter had a decreased cytochrome content.

INTRODUCTION

Dimorphic fungi such as *Paracoccidioides brasiliensis* (Carbonell, Kanetsuna & Gil, 1970), *Mucor rouxii* (Bartnicki-Garcia, 1963) and *Candida albicans* (Chattaway et al., 1973) are being used increasingly as experimental material in the study of microbial differentiation. These organisms are capable of growing either as a hypha or in a unicellular yeast-like form. The deuteromycete *Aureobasidium pullulans* has been studied for a number of years as the source of a novel extracellular polysaccharide, pullulan, and the conditions affecting synthesis of the polysaccharide have been examined (Bender, Lehmann & Wallenfels, 1959; Catley, 1971, 1973). This fungus has been described as being dimorphic (Cooke, 1959) though in reality the sequence of transformations undergone by the organism is more complex (Ramos & Garcia-Acha, 1975). In this laboratory we have been examining metabolic events associated with the differentiation of this organism in liquid culture, e.g. the metabolism of pullulan, trehalose and ethanol have been investigated (Kelly & Catley, 1976; Catley & Kelly, 1975; Carolan, Catley & Kelly, 1976).

Recent experiments with *Mucor* and *Mycotypha* have demonstrated a relationship between dimorphism and the respiration-fermentation balance (Hall & Kolankaya, 1974). Environmental conditions which lead to an impairment of respiratory function, e.g. high glucose concentration, KCN and oligomycin, also lead to an increase in the number of yeast-like organisms. Spontaneous and ultraviolet light-induced mutants have also been isolated. These mutants show an impaired respiratory chain and grow entirely in the yeast-like phase (Storck & Morrill, 1971; Schulz, Kraepelin & Hinkelmann, 1974).

Because there is accumulating evidence that the elaboration of pullulan is associated with the yeast-like phase of *A. pullulans* (Catley, 1973; Catley & Kelly, 1975), we decided to investigate the possibility of producing mutants of *A. pullulans* which grew with an increased

* Present address: Department of Developmental Biology, Boston Biomedical Research Institute, 20 Staniford Street, Boston, Massachusetts 02114, U.S.A.
proportion of single cells in the hope that there would be a concomitant increase in the amount of pullulan produced. For this purpose we selected the mutagen ethidium bromide (2,7-diamino-10-ethyl-9-phenylphenanthridinium bromide) which is thought to have a selective action on circular DNA, such as mitochondrial DNA in eukaryotic cells, in order to suppress the growth of the presumed respiratory mycelium.

METHODS

Organism and culture conditions. Aureobasidium pullulans strain ATCC9348 was grown in medium of the following composition: glucose, 250 mM; KCl, 5.0 mM; MgCl2, 4.0 mM; Na2SO4, 4.0 mM; Na2HPO4 and NaH2PO4, 20 mM; NH4Cl, 20 mM; FeCl3, 6H2O, 2.0 µM; MnCl2.4H2O, 2.0 µM; ZnCl2, 2.0 µM; CaCl2, 50.0 µM; CuSO4, 5H2O, 0.2 µM; and yeast nitrogen base (Difco) 0.65 % (w/v). An inoculum was prepared by suspending the organism, grown on potato dextrose agar, in sterile water. The inoculum was grown in 100 ml of the above medium for 48 h at 25°C and 2 ml of this culture was then used to inoculate a further 100 ml of medium.

Mutagenesis. A sample (10 ml) of an 18 h culture was transferred aseptically to 90 ml of the standard medium containing 40 µg ethidium bromide ml−1. The culture was incubated at 22°C for 4 h, centrifuged (5000 g, 10 min) and washed in sterile growth medium without glucose. Samples were removed, spread on 2 % (w/v) agar plates containing the standard growth medium and incubated at 25°C for 3 days. Those colonies displaying an apparent increase in the proportion of yeast-like cells were replated.

Analytical methods. Cell dry weights were determined by passing culture samples through pre-weighed cellulose acetate filters (Millipore, 0.8 µm pore size), washing the filters with ice-cold distilled water and drying them in vacuo at 45°C. Yeast-like cells were counted in a Thoma haemocytometer. Extracellular polysaccharide was precipitated from cell-free supernatant samples by adding 2 vols ethanol. The samples were stored overnight at 4°C and the precipitate was collected and washed with 66 % (v/v) ethanol until free of glucose. The polysaccharide was redissolved in distilled water at 100°C. Total carbohydrate was determined by the phenol–sulphuric acid method (Dubois et al., 1956); pullulan was estimated with pullulanase (Catley, 1971). Ethanol was determined by gas–liquid chromatography of 1 µl supernatant samples using a Perkin–Elmer gas chromatograph (model F17), with detector, injector and oven temperatures of 187, 270 and 60°C, respectively, and a stationary phase of 15 % carbowax 1500 on florisoril.

Whole-cell spectrophotometry. Organisms were either grown as described above or in the same medium containing 55 mM-glucose for 18 h at room temperature. Samples were removed from both cultures and centrifuged (10000 g, 10 min). The cells were then resuspended in a small quantity of distilled water to form a heavy cell paste and the suspension was divided between two 1 cm path-length cuvettes. Difference spectra were taken for the two cuvettes using a split-beam spectrophotometer (Haddock & Garland, 1971) with (i) no additions in order to obtain a baseline, (ii) H2O2 added to one cuvette to obtain a reduced–oxidized difference spectrum. Whole-cell protein was determined by the method of Miller (1959). The extinction coefficients used in the calculation of cytochrome concentrations are those given by Boveris et al. (1971).

RESULTS

Ethidium bromide mutagenesis yielded several colonies which appeared to exhibit a higher proportion of yeast-like cells. Three were selected, designated Y3, Y7 and Y8, and their growth, cell-type and polysaccharide production were compared with the wild type (Figs 1 and 2). Although the increase in cell dry weight was similar for all four isolates the number of yeast-like cells produced differed markedly. Moreover, Fig. 2 shows that the number of yeast-like cells was closely related to the concentration of extracellular polysaccharide, a product which has pullulan as a major component. The nature of the remaining extracellular polysaccharide(s) is not known but is currently under investigation.

Whole-cell cytochrome scans for the wild type and mutant isolates of A. pullulans are shown in Fig. 3. Absorbance maxima of the difference spectrum were found at about 425, 445, 522, 552 and 612 nm. The peak at 425 nm probably represents a combination of the γ absorption bands for cytochromes b and c, and the peak at 445 nm the absorption band for c-type cytochromes with a contribution from cytochrome b at about 560 nm. The absorption peak at 612 nm represents the α absorption band for cytochromes a+a3. Most
Ethidium bromide mutagenesis of *A. pullulans*

It is known that ethidium bromide mutagenesis led to a decrease in the level of cytochromes, particularly cytochromes $a + a_3$. This is also found in *Saccharomyces cerevisiae* (Slonimski, Perrodin & Croft, 1968).

cytochrome scans show a pronounced negative trough at about 475 nm representing the flavoprotein components of the respiration chain. This trough was much less pronounced in *A. pullulans*. Again, published scans show the relative intensities of the absorption peaks at 425 nm and 445 nm to be the reverse of that found in *A. pullulans*. The concentrations of the $a$, $b$ and $c$-type cytochromes were calculated (Table 1) and may be compared with the values given for *Candida parapsilosis* by Kellerman, Biggs & Linnane (1969). Ethidium bromide mutagenesis led to a decrease in the level of cytochromes, particularly cytochromes $a + a_3$. This is also found in *Saccharomyces cerevisiae* (Slonimski, Perrodin & Croft, 1968).

* Data from Kellerman et al. (1969).
A plot of the number of yeast-like cells produced by these mutants against their cytochrome a+a₃ content showed an inverse relationship.

Further comparisons of the wild type and mutant Y8 were undertaken. The rates of increase in cell dry weight were again similar, as were the rates of glucose uptake (0.20 μmol mg⁻¹ h⁻¹ for the wild type and 0.16 μmol mg⁻¹ h⁻¹ for Y8). However, the wild-type culture excreted ethanol into the medium with the concentration rising to 43 mM whereas ethanol could not be detected in the mutant Y8 culture at any stage of growth.

**DISCUSSION**

Of the mutants produced by the treatment of *A. pullulans* with ethidium bromide, three were selected for their apparent increase in yeast-like growth on agar plates. A comparison of the yeast cell numbers and cell dry weights with those of the untreated organism showed that the proportion of growth in the yeast-like form was considerably greater in the mutants. The finding that ethidium bromide treatment produces mutants with decreased amounts of hyphae might suggest that the mycelial growth of *A. pullulans* is dependent on mitochondrial function, since the action of the mutagen is thought to result in the impairment of transcription from the circular duplex of mitochondrial DNA (Radloff, Bauer & Vinograd, 1967). Ethidium bromide, however, affects other cellular functions and its actions may be more complex (Azzi & Santato, 1971; Jones & Kearns, 1975). Whatever the action of the mutagen, its effect on *A. pullulans* is to shift the balance of growth from the mycelial to the yeast phase.

Investigations of dimorphism in *Mycotypha* (Storck & Morrill, 1971; Schulz et al., 1974; Hall & Kolankaya, 1974) have demonstrated a relationship between dimorphism and the respiration–fermentation balance. It was therefore decided to see if there might not be a similar connexion between these metabolic alternatives and the morphological change observed in *A. pullulans*. The cytochrome content of the mutant yeast cells is considerably reduced, suggesting that respiration may not be necessary for the functioning of the yeast cell but is necessary for the viability of the mycelium. However, for glycolysis to take place, a fermentative metabolism requires the production of some compound reduced by NADH. Whilst there is considerable production of ethanol during growth of the wild type, with the concentration exceeding 40 mM (Catley & Kelly, 1975; Carolan et al., 1976), there was no detectable ethanol at any point of the growth cycle of mutant Y8. Contrary to the above, this indicates either a respiratory metabolism for the mutant yeast or a fermentation product that is not ethanol. The levels of cytochromes are reduced, but not absent, and may be sufficient for adequate respiration.

Evidence has been presented (Catley, 1973; Catley & Kelly, 1975) that the production of pullulan occurs in the early-stationary phase of the growth cycle and is concomitant with a change of morphology by the organism from mycelial to yeast-like growth. The results presented here show that an increased production of yeast cells by the organism is paralleled by an increased production of pullulan, again linking the elaboration of the extracellular polysaccharide to the yeast cell.

We are currently investigating the balance between oxidative and fermentative metabolism in the wild type and mutant organisms in the hope of establishing further links between morphology, glucose utilization patterns and pullulan production in *A. pullulans*.

We thank the Science Research Council for a graduate studentship to P.J.K., and Professor P. B. Garland for access to the spectrophotometer used in these studies. Dr B. Haddock is also thanked for his help in the interpretation of the difference spectra.
