(Received 7 February 1979)

According to Passow & Rothstein (1960), the mercury-induced loss of K\(^+\) from yeast cells is an all-or-none effect. This hypothesis was tested by analysing individual yeast cells by means of energy-dispersive X-ray microanalysis. A dual effect of mercury was observed. The cell population was split into two parts: one part consisted of cells that had suffered a (nearly) complete loss of K\(^+\) – the number of these cells increased with increasing concentrations of HgCl\(_2\); the other consisted of cells that had only lost part of their K\(^+\) content – these cells showed a normal distribution around a central value that decreased with increasing concentrations of HgCl\(_2\). Our analysis shows that the effect of mercury is more complex than originally suggested and that, in addition to an all-or-none effect, a gradual loss of K\(^+\) occurs.

INTRODUCTION

Passow & Rothstein (1960) have demonstrated that interaction of inorganic mercury with yeast cells results in a leakage of K\(^+\) and anions to the suspending medium. They suggested that this K\(^+\) loss is an all-or-none effect for individual cells, each cell having a certain threshold concentration for mercury at which a complete loss of K\(^+\) occurs. An increase in the HgCl\(_2\) concentration results in an increase in the number of cells that suffer a complete loss of K\(^+\) and consequently an increase in the K\(^+\) concentration of the suspending medium.

The elemental content of individual cells can be measured by means of electron probe X-ray microanalysis (Lechene et al., 1977). This technique is based on the detection and recording of X-rays generated within the specimen by the electron beam, each element present in the specimen giving rise to X-rays of a specific energy (Chandler, 1977). Analysis of a considerable number of cells is necessary to determine whether a gradual or an all-or-none effect is involved in K\(^+\) leakage. Roinel (1977) showed the applicability of X-ray microanalysis to problems of this type in a study of the effect of lead on erythrocytes.

In the present study, the effect of inorganic mercury on the K\(^+\) content of yeast cells was examined by X-ray microanalysis. We conclude that both a gradual and an 'all-or-none' response occurred.

METHODS

Incubation. Yeast cells of Saccharomyces cerevisiae strain Delft II were starved under aeration for 20 h. After starvation, the cells (2\%\(, w/v\)) were resuspended in distilled water adjusted to pH 4.0 with HCl. The non-metabolizing yeast cells were incubated for 5 h at 25°C with HgCl\(_2\) at various concentrations. Nitrogen...
was bubbled through the suspension continuously. At appropriate times, 4 ml samples were taken and centrifuged, and the supernatant was decanted. The Na⁺ and K⁺ concentrations in the supernatant were determined by flame spectrophotometry. The phosphorus content of the supernatant was determined by the method of Fiske & Subbarow (1925).

Preparation of the cells. After 5 h incubation, the cells were washed twice with distilled water (pH 5-6) and resuspended in distilled water. The cell suspension was sprayed through a glass capillary tube (internal diam. about 0.5 mm) on to polished pure carbon plates. To demonstrate that no loss of cell K⁺ occurred during washing in distilled water, the supernatant from the washed suspensions was analysed by flame spectrophotometry. The carbon support was exposed to the spray for about 5 s at a distance of 20 cm. The cells were air-dried on the support and then stored under vacuum at room temperature. The specimen was coated with a carbon layer to improve conductivity and, to prevent rehydration, it was kept under vacuum until analysis.

**Electron probe X-ray microanalysis.** Analysis was performed with an EDAX energy-dispersive spectrometer in combination with a Philips PSEM 500 scanning electron microscope. The carbon support was mounted on an aluminium specimen holder. The carbon plate had a larger diameter than the aluminium holder so that the production of stray X-rays from the aluminium holder was avoided. Analysis was carried out at an accelerating voltage of 25 kV and a spot size of 0.25 μm. The specimen was tilted 20° with respect to the electron beam. Calculations on the X-ray spectrum were carried out with the EDIT 7 EM software system.

**RESULTS**

Yeast cells used in this study contained about 250 mmol K⁺ per 1 cell water. The yeast cell is relatively impermeable to cations. If cells are suspended in distilled water, only a very small leakage of K⁺ occurs: in resting cells, a steady state concentration gradient of about 1750:1 is maintained (see Fig. 1).

Passow & Rothstein (1960) showed that inorganic mercury caused a breakdown in the permeability barrier to K⁺: thus incubation of non-metabolizing cells in the presence of HgCl₂ resulted in a large efflux of K⁺ from the cells into the medium. Figure 1 shows that HgCl₂ caused a K⁺ leakage from yeast cells. The amount of K⁺ that leaked out of the cells after 5 h incubation was dependent on the HgCl₂ concentration; at HgCl₂ concentrations above 0.4 mM, almost all the cell K⁺ was lost. The time course of the leakage was also dependent on the HgCl₂ concentration; the half-time of the K⁺ efflux decreased from 90 min with 0.11 mM-HgCl₂ to only 10 min with 0.8 mM-HgCl₂.

Analysis of the supernatants from the washed cell suspensions showed that K⁺ loss as a result of washing in distilled water was very small. Furthermore, there was no measurable Na⁺ leakage from the cells during the mercury treatment. Phosphorus leakage was found to be negligible; at 0.8 mM-HgCl₂, only 4% of the total internal phosphorus content leaked out of the cells.

During incubation of yeast cells in HgCl₂, a pH change of the suspending medium was observed, which was dependent on the HgCl₂ concentration and the incubation time (Fig. 2). A maximum in the pH curves was observed, and this maximum was also dependent on the HgCl₂ concentration.

After 5 h incubation at a given concentration of HgCl₂, the yeast cells were mounted on a carbon plate by spraying (see Methods); this gave a large number of well separated cells. Scanning electron microscopy of the mercury-treated cells showed no obvious differences between or within cell populations. It should, however, be remarked that we examined carbon-coated specimens only, so that no optimal image was obtained.

The yeast cells were examined by means of electron probe X-ray microanalysis. The carbon plate produced only low background X-ray intensity. X-ray signals from P, S, Cl and K were found only in cells and not in adjacent areas of the support. Typical X-ray spectra of yeast cells incubated in 0.13 mM-HgCl₂ are shown in Fig. 3.

Variations in cell size will be reflected in the absolute intensities of the characteristic K and P signals. Since the electron beam penetrates the yeast cells completely, part of the

voltage of 12 kV.

observed spectrum is due to the carbon support, which will contribute to the background;  
hence, the background intensity cannot be used to correct for specimen mass thickness  
(Hall, 1971). We therefore chose to express the results of the analysis as the ratio between  
the observed intensities of the K and P signals, assuming that the intensity of the P signal  
is a good measure of cell volume. This ratio is less sensitive to differences in cell volume and  
experimental conditions such as beam current than the absolute values of the peak intensities  
for K and P.

About 150 cells of each population incubated at a given HgCl₂ concentration were  
analysed. The histogram of the probe readings of control cells showed a single population,  
with a normal distribution around a central value of 1-51 (Fig. 4a). Treatment of the yeast  
cells with HgCl₂ appeared to have a dual effect. After treatment with 0-1 to 0-2 mM-HgCl₂,  
the cell population was split in two parts; cells of one part lost some K⁺, while the others  
lost almost all their K⁺ (Fig. 4b, c, d). At concentrations of 0-22 mM-HgCl₂ and above, all  
cells had lost virtually all their K⁺.

Fig. 6. Distribution of the K/P ratio in a population of yeast cells treated with 0·11 mM-HgCl₂ in 10 mM-NaCl.

The K⁺ leakage was stimulated in the presence of Na⁺ or Mg²⁺. However, the stimulation of the mercury-induced K⁺ efflux by these cations was in contrast with the finding that resting cells lost less K⁺ during washing in 10 mM-NaCl or MgCl₂ at pH 4·0 than in distilled water at pH 4·0. K⁺ efflux in both 10 mM-NaCl and distilled water (pH 4·0) is shown in Fig. 5. In a parallel experiment it was found that the maximum pH value of the supernatant attained during incubation in 10 mM-NaCl was lower than that in distilled water. The results of the analysis of cells treated with 0·11 mM-HgCl₂ in 10 mM-NaCl (Fig. 6) again indicate two populations. However, compared with the cells treated with the same HgCl₂ concentration in water, the mean K/P ratio in that part of the cell population that had lost some K⁺ was decreased, whereas the number of cells that had lost all K⁺ was increased.

In Fig. 7, the final K⁺ concentration in the incubation medium, as measured by flame

spectrophotometry, is plotted as a function of the HgCl\(_2\) concentration. The loss of K\(^+\) as calculated from the microprobe analysis of the individual cells is also shown. These observations are in good agreement with each other.

We also tested the thiol reagent N-ethylmaleimide and some metal cations for their ability to induce K\(^+\) efflux from yeast cells. N-Ethylmaleimide was not very effective; a concentration of 2 mM was needed to induce a loss of 20\% of the total K\(^+\) content of the cells. Cu\(^{2+}\) was nearly as effective as Hg\(^{2+}\); after 4 h incubation, 0.06 mM-CuCl\(_2\) caused a K\(^+\) loss of about 90\% of that caused by the same concentration of HgCl\(_2\). Zn\(^{2+}\) was much less effective; 5.5 mM-ZnCl\(_2\) was needed to obtain a K\(^+\) loss comparable to that caused by 0.11 mM-HgCl\(_2\). CdCl\(_2\) did not cause any appreciable leakage of K\(^+\).

**DISCUSSION**

The method of preparation of yeast cells for microanalysis used in this study permits the analysis of a large number of cells. Air-drying appears to be an adequate method for retaining K\(^+\) in the cells, as was shown by Chandler & Battersby (1976) for spermatozoa and by Lechene *et al.* (1977) for erythrocytes.

The results of our analysis (Fig. 4) show that two effects of mercury can be distinguished. At first, each cell in the population seems to respond in a graded fashion to increasing concentrations of HgCl\(_2\), but, when a certain threshold is attained, the cell loses all internal K\(^+\). Thus our findings are in agreement with the suggestion of Passow & Rothstein (1960) that with increasing concentrations of HgCl\(_2\), an increasing number of yeast cells lose all internal K\(^+\). In contrast with their suggestion, however, we found that K\(^+\) loss is not only an all-or-none process, but that in addition a gradual loss occurs that is related to the mercury concentration. The mechanism of mercury-induced K\(^+\) loss from yeast cells appears to be more complex than the lead-induced K\(^+\) loss from erythrocytes, studied by Roinel (1977) with X-ray microanalysis; in that case, a simple all-or-none response was observed.

In order to maintain electroneutrality, the efflux of K\(^+\) will be accompanied by an influx...
of cations and/or an efflux of cell anions. The pH change of the medium during incubation with HgCl₂ (Fig. 2) suggests a concomitant proton influx. However, it appears that mercury induces not just a simple stoichiometric K⁺–H⁺ exchange, but much more complex ion-fluxes. The form of the pH curves compared with the K⁺ efflux curves (Figs 1, 2) suggests an additional anion efflux, because H⁺ influx is insufficient to account quantitatively for the charge balance. Leakage of organic acids from the cells could explain the decrease in pH at higher mercury concentrations. In addition, the experiments showing an increased efflux of K⁺ in a medium containing NaCl (see Fig. 5) suggest the possibility of an exchange of K⁺ with cations from the medium (in this case Na⁺). Other interactions of mercury with the yeast cell may also occur, e.g. reaction with SH groups, leading to production of protons. The initial decrease in net H⁺ influx observed at low mercury concentrations might be related to such interactions.

The biochemical action of heavy metals has been extensively reviewed (Passow et al., 1961; Vallee & Ulmer, 1972). Mercury has an especially strong affinity for thiol groups, copper is also a thiol reagent, while zinc and cadmium have a high affinity for the imidazole group (Boyer, 1959; Gurd, 1954). N-Ethylmaleimide is a thiol reagent with a much lower specificity.

Passow & Rothstein (1960) suggested that inorganic mercury interacted with SH groups of proteins in the yeast cell membrane that are involved in maintaining the permeability barrier for K⁺. Shieh & Barber (1973) found that HgCl₂ above a certain concentration caused a net efflux of K⁺ in Chlorella. They suggested that mercury may produce conformational changes in the membrane and in some way affect a macromolecular carrier. Our results also suggest that the increase in K⁺ permeability is associated with the reaction of mercury with SH groups within the yeast cell membrane, but it is unclear how the gradual and total K⁺ loss, respectively, are related to the interaction of mercury with the yeast cell.

We are grateful to Dr A. M. Stadhouders, Department of Submicroscopic Morphology, University of Nijmegen, for putting the electron microscope at our disposal. We also wish to thank Dr G. W. F. H. Borst-Pauwels for valuable criticism. This study was supported in part by a grant from the Netherlands Organisation for the Advancement of Pure Research (Z.W.O.) through the Netherlands Foundation for Biophysics. The yeast was kindly supplied by Gist-Brocades at Delft.
