Mitotic Arrest and Chromosome Doubling Using Thiabendazole, Cambendazole, Nocodazole and Ben Late in the Slime Mould Dictyostelium discoideum

By D. L. WELKER AND K. L. WILLIAMS*

Genetics Department, Research School of Biological Sciences, Australian National University, P.O. Box 475, Canberra City, A.C.T. 2601, Australia

(Received 21 March 1979)

Thiabendazole and cambendazole induced mitotic arrest and isogenic diploid formation through chromosome doubling in amoebae of the cellular slime mould Dictyostelium discoideum grown either axenically or in a bacterial suspension. The effect of nocodazole on axenically grown cells was similar to that of thiabendazole and cambendazole, but with cells grown on bacteria nocodazole was a much less effective inducer of mitotic arrest and did not lead to isogenic diploid formation. Benomyl, the active ingredient of ben late, had little or no effect on the induction of mitotic arrest and was a poor inducer of isogenic diploids in cells grown either axenically or on bacteria. All four benzimidazole derivatives were effective in haploidizing pre-existing diploids.

INTRODUCTION

Several studies have recently been aimed at determination of the karyotype of the cellular slime mould Dictyostelium discoideum (Robson & Williams, 1977; Zada-Hames, 1977; Brody & Williams, 1974; Sussman, 1961). These investigations have been hampered, however, by the inability to obtain large numbers of cells in metaphase. While the number of cells in metaphase can be increased by treatment with colchicine at high concentrations (Zada-Hames, 1977) or by release from starvation (Robson & Williams, 1977), these techniques have not greatly facilitated routine chromosomal studies particularly with cells growing on bacteria.

In an attempt to find a simple and inexpensive method of obtaining large numbers of mitotically arrested cells and of producing isogenic diploids through chromosome doubling, we have investigated the effects of several benzimidazole derivatives on D. discoideum. Benzimidazole derivatives, in particular methyl benzimidazol-2-yl-carbamate (MBC) which is a decomposition product of benomyl (Clemons & Sisler, 1969), have antimitotic activity in fungi such as Aspergillus nidulans and Ustilago maydis (Davidse, 1973; Davidse, 1975; Davidse & Flach, 1977; Hammerschlag & Sisler, 1973), in mammalian cells (Styles & Garner, 1974; Seiler, 1975) and in higher plants (Zutshi & Kaul, 1975). Benzimidazoles have been widely used as fungicides (benomyl, thiabendazole, cambendazole), as anthelminthics (thiabendazole) and as antitumour drugs (nocodazole, also called oncodazole). Structural formulae of the compounds used in this investigation are presented in Fig. 1.

We report the effect of the benzimidazole derivatives benomyl, cambendazole, nocodazole and thiabendazole on the induction of metaphase arrest and isogenic diploid formation in D. discoideum. While this work was in progress, the use of nocodazole as a mitotic inhibitor in D. discoideum was described by Cappuccinelli et al. (1979).
METHODS

Culture of amoebae of D. discoideum. The haploid strain AX3 (Loomis, 1971) was used in all experiments in which the effect of the benzimidazole derivatives on the induction of mitotic arrest and isogenic diploid formation was investigated. Strain DU319 (Williams & Barrand, 1978) was used to determine the effects of the benzimidazole derivatives on haploidization of pre-existing diploids. Stocks of these strains were maintained on SM agar (Sussman, 1966) in association with a cobalt-resistant strain of Klebsiella aerogenes at 21 ± 1 °C (Williams & Newell, 1976). Amoebae were grown axenically in 25 ml of the medium of Watts & Ashworth (1970) in 125 ml flasks on an orbital shaker (150 cycles min⁻¹) at 21 ± 1 °C. Exponentially growing amoebae were diluted to approximately 10⁶ amoebae ml⁻¹ with fresh axenic medium for these experiments. For experiments with bacterially grown amoebae, the cultures were grown overnight to between 3 × 10⁶ and 4 × 10⁶ amoebae ml⁻¹ in suspension with Escherichia coli B/r (about 10⁶ bacteria ml⁻¹) in phosphate buffered saline (Deering et al., 1970) and then diluted to 10⁶ amoebae ml⁻¹ with fresh E. coli suspension. The bacterial suspensions (5 to 20 ml) were rotated at 150 cycles min⁻¹ in 125 ml flasks at 21 ± 1 °C. In some experiments amoebae were grown on suspensions of autoclaved E. coli (with 250 µg dihydrostreptomycin sulphate ml⁻¹) either with or without the addition of 10% (v/v) of a filter-sterilized solution of Oxoid yeast extract (70 g l⁻¹) and Oxoid bacteriological peptone (140 g l⁻¹).

Chemicals. Ben late, a mixture of 50% benomyl and 50% kaolinite, was obtained from DuPont (Australia) Ltd, North Sydney, N.S.W., Australia. Cambendazole and thia bendazol e (both 97% pure) were the gift of William Bliss of Merck, Sharp & Dohme Research Labs, Ingleburn, N.S.W., Australia. Nocodazole was obtained from Aldrich Chemical Co., Milwaukee, Wisconsin, U.S.A. Stock solutions were prepared in dimethyl sulphoxide (DMSO; Sigma grade 1) and kept frozen at −10 °C until use (ben late, 50 mg ml⁻¹; cambendazole, 50 mg ml⁻¹; thia bendazole, 10 mg ml⁻¹; nocodazole, 5 mg ml⁻¹). In early experiments, fresh aqueous suspensions of ben late were used; the results obtained, although consistent with those reported here, were more variable presumably due to inadequate dispersal of the ben late.

Cytological examination. Amoebae were fixed in methanol/acetic acid (3:1, v/v) and air-dried on to slides as described previously (Brody & Williams, 1974). The cells were either stained for 15 min with 10% (v/v) Gurr's Giemsa stain (Improved R66) in 0-07 M-Sorensen's phosphate pH 6-8, or, in most cases, treated with 0-25% (w/v) trypsin (Difco, 1:250) in 0-85% (w/v) NaCl for 90 s and then stained with Giemsa stain for 30 min. The trypsin treatment was included to reduce cytoplasmic staining so that interphase nuclei could be

**Fig. 2.** The mitotic index (○), percentage of diploid colonies (●) and plating efficiency (□) of axenically grown amoebae of strain AX3 treated with thiabendazole (a), cambendazole (b), nocodazole (c) or ben late (d).

Easily observed by light microscopy (Robson & Williams, 1977). The mitotic index was determined by examining all nuclei in a series of randomly chosen fields; at least 1000 nuclei were examined for each sample.

**Photography.** Either Kodak Panatomic X or Copex Pan rapid film was used (Galeotti & Williams, 1978).

**Haploidization.** Amoebae of diploid strain DU319 were plated clonally on to media containing the appropriate inhibitor. Agar containing ben late was prepared by adding a concentrated aqueous suspension of ben late to SM agar after autoclaving and cooling to 60 °C (Williams & Barrand, 1978). Agars containing cambendazole, nocodazole and thiabendazole were prepared by adding appropriate volumes of inhibitor/DMSO stock solutions to SM agar after autoclaving and cooling to 60 °C. The concentration of DMSO in these plates was less than 0-1% (v/v) at the time of inoculation.

**Determination of plating efficiency.** Cell viability was measured by determining the ability of the amoebae to divide and form visible colonies in bacterial lawns on the surface of SM agar plates. Samples of the cell suspensions were removed after treatment with inhibitor for various times and diluted so as to obtain about 50 colonies per plate.

**Determination of ploidy.** Ploidy was routinely determined by examination of the size and shape of spores taken from individual colonies obtained in plating efficiency experiments. Spores were removed from fruiting bodies with sterile toothpicks, suspended in distilled water or Bonner's salt solution in 60-well Falcon 3034 microtest tissue culture plates and then examined using an Olympus BH microscope at 400× magnification. In some cases, ploidy was confirmed by cytological examination of chromosomes using either axenically or bacterially grown cells. For rapid cytological examinations, amoebae were removed from the edge of colonies growing on SM agar, suspended with *E. coli* B/r, treated with thiabendazole (10 μg ml⁻¹) for 2-5 h at 21 °C with shaking at 150 cycles min⁻¹, fixed and then stained as described above.

**RESULTS**

**Effects of benzimidazole derivatives on axenically grown amoebae**

The mitotic index of axenically growing cells of AX3 increased from 1-9% to between 30 and 40% within 5 to 7 h exposure to thiabendazole (10 μg ml⁻¹), cambendazole (50 μg ml⁻¹) or nocodazole (7 μg ml⁻¹) and then decreased to between 1 and 10% by 15 h (Fig. 2a, b, c). Ben late (100 μg ml⁻¹) had little effect on the mitotic index (Fig. 2d), since the maximum mitotic index obtained for ben late-treated cells was 3-3% (7 h). Controls with or without DMSO, used at the concentration added with inhibitors (0-1%, v/v), gave the same mitotic index (1-9%, mean of five experiments).

* Includes two possible triploids out of 22 diploids seen.

A decrease in viability (as measured by plating efficiency) and an increase in isogenic diploid formation (Fig. 2a, b, c) coincided with the decrease in the mitotic index of thiabendazole-, cambendazole- or nocodazole-treated cells. The plating efficiency of these cells decreased to between 2 and 15 % by 15 h. The plating efficiency of benlate-treated cells did not decrease for at least 50 h (Fig. 2d). After 7 h the proportion of surviving cells giving rise to diploid colonies increased and reached a plateau of greater than 40 % for thiabendazole-, cambendazole- and nocodazole-treated cells (Fig. 2a, b, c). With benlate, the percentage of diploids reached a plateau at about 5 % (Fig. 2d). Diploids were observed among colonies obtained from the untreated control cultures at a frequency of less than 0.1 % (2 of 3400 colonies scored). At the concentrations used in the above experiments, cell division was blocked with thiabendazole, cambendazole and nocodazole and on average less than one round of cell division occurred following exposure to benlate (Fig. 3). At lower concentrations of the inhibitors the effects on growth arrest, mitotic index, plating efficiency and chromosome doubling were less marked. For example, with thiabendazole at 1 µg ml\(^{-1}\), the growth rate was similar to that of control cultures and the mitotic index was slightly increased (4-2 %, 7-25 h) but isogenic diploids were not formed nor was the plating efficiency lowered. Following exposure to thiabendazole at 5 µg ml\(^{-1}\), only one round of cell division occurred and the mitotic index increased to 21 % at 7-25 h; however, after 48 h the plating efficiency remained above 20 % and only 4 % of colonies were diploid.

The appearance of aneuploid nuclei increased with time in cultures treated with thiaben-

These were found in axenic cultures of strain AX3 treated with 10 μg thiabendazole ml\(^{-1}\) for 17 h. Bar markers represent 2 μm.

dazole (Table 1), cambendazole or nocodazole. Initially, all mitoses were haploid \((n = 7)\), then the percentage of aneuploid (between 8 and 13 chromosomes) and diploid \((2n = 14)\) mitotic figures increased. Aneuploid mitoses reached a plateau of about 40% after 14 h; this coincided with the fall in plating efficiency (Fig. 2a). Aneuploid nuclei frequently occurred as pairs within the same cytoplasm. Examples of these are shown in Fig. 4(a) (6+8 chromosomes), Fig. 4(b) (9+5 chromosomes) and Fig. 4(c) (10+4 chromosomes). Aneuploids were rarely seen in control or ben late-treated cultures. No aneuploid strains were isolated when cultures containing aneuploid mitotic nuclei were plated on SM agar.

**Effects of benzimidazole derivatives on bacterially grown cells**

The concentrations of thiabendazole and cambendazole used in experiments with cells growing in axenic medium had similar effects on cells growing on bacteria. The mitotic index of bacterially grown cells treated with thiabendazole was greater than 30% by 3 h and then decreased (Fig. 5). This result is consistent with the result for cells growing in axenic medium considering the shorter generation time of bacterially grown cells (3.5 h as compared to 10 h). Cell division was again inhibited, although approximately one round of cell division occurred by 12 h (Fig. 6). After 24 h the cell number gradually decreased (results not shown). Cells treated with either thiabendazole or cambendazole varied greatly in size from at least twice the diameter of untreated cells to very small dark cells. A decrease in plating efficiency and an induction of isogenic diploids similar to those seen with axenically grown cells were also observed with bacterially grown cells treated with thiabendazole (Fig. 7a) or cambendazole (Fig. 7b). The formation of isogenic diploids coincided with the decrease in plating efficiency. The proportion of diploids reached a peak of greater than 50% at 12 h for cells treated with thiabendazole and then declined to 25% by 24 h (Fig. 7a). For cambendazole-treated cells, the percentage of diploids reached a maximum between 12 and 24 h (Fig. 7b); by 48 h the percentage of diploids had fallen to 25%. Control cultures remained haploid throughout and had plating efficiencies above 80%.

Nocodazole at 7 μg ml\(^{-1}\) had no effect on the doubling time of cells growing on bacteria (Fig. 6). The mitotic index increased to only 9% by 2 h and then decreased (Fig. 5). No isogenic diploids were recovered from bacterially grown cells treated with nocodazole nor was there any apparent effect on plating efficiency, which at all times was greater than 80%.

Ben late at 100 μg ml\(^{-1}\) increased the doubling time of cells growing on live bacteria to 5 h (Fig. 6) and decreased the plating efficiency to about 40% by 24 h. Diploids were rarely recovered, if at all, from ben late-treated cells grown on live bacteria.

**Effect of ben late on cells grown on autoclaved bacteria**

After much trial and error, conditions were found under which ben late induced a high frequency of isogenic diploids. These were prolonged incubation following growth on autoclaved bacteria in the presence of ben late at 100 μg ml\(^{-1}\) with yeast extract and bacteriological peptone. Under these conditions the percentage of isogenic diploids rose to 27\% by 96 h. Without the addition of yeast extract and peptone the proportion of diploids induced by ben late at 100 μg ml\(^{-1}\) was only 5\% at 96 h (Fig. 8). Cell doubling times on autoclaved bacteria were about 6 h for both control and ben late-treated amoebae with or without the addition of yeast extract and peptone. By 48 h, the control and ben late-treated cells reached stationary phase at greater than 10\(^7\) cells ml\(^{-1}\) from initial concentrations of 4.5 × 10\(^5\) cells ml\(^{-1}\). The plating efficiency of the ben late-treated cells both with and

* These compounds were added to molten SM agar after autoclaving as a powder (ben late) or dissolved in DMSO (thiabendazole, 10 mg ml⁻¹; cambendazole, 50 mg ml⁻¹; nocodazole, 5 mg ml⁻¹).
† Plating efficiency as a percentage of that on SM agar. Diploid DU319 has a plating efficiency of about 70% on SM agar.

without yeast extract and peptone decreased to about 40% at 96 h (Fig. 8) but remained above 70% for control cells (data not shown).

Haploidization of pre-existing diploids

Ben late has previously been shown to be an effective haploidizing agent for *D. discoideum* (Williams & Barrand, 1978). At 20 µg ml⁻¹ ben late induced between 90 and 100% haploidization of the diploid DU319 while decreasing the plating efficiency to about 20%. Thiabendazole (2 µg ml⁻¹), cambendazole (10 µg ml⁻¹) or nocodazole (5 µg ml⁻¹) also induced between 90 and 100% haploidization of DU319 while lowering the plating efficiency to between 15 and 50% (Table 2). Lower concentrations of thiabendazole (1 µg ml⁻¹), cambendazole (5 µg ml⁻¹) or nocodazole (2 µg ml⁻¹) were not as effective at inducing haploidization and did not affect plating efficiency. Higher concentrations of thiabendazole (5 µg ml⁻¹) or cambendazole (20 µg ml⁻¹) also induced haploidization but decreased the plating efficiency further.
DISCUSSION

The benzimidazole derivatives used in this study were found to have five effects on *D. discoideum*: (i) the induction of mitotic arrest; (ii) the induction of isogenic diploids through chromosome doubling; (iii) the haploidization of pre-existing diploids; (iv) the lowering of plating efficiency; and (v) the inhibition of cell division. The first four effects can be directly attributed to a disruption of the mitotic spindle which would, in turn, affect the separation of chromosomes and lead to the induction of polyploids and aneuploids through non-disjunction. The decrease in plating efficiency is most likely due to the increase in aneuploidy observed in these experiments, and not to a 'deterioration of chromosomal structure' (Cappuccinelli *et al.*, 1979); cultures with high frequencies of aneuploids have previously been observed to have low plating efficiencies due presumably to low viability of aneuploid cells. No aneuploid strains have been reported (Brody & Williams, 1974). Antimitotic effects of MBC have been found previously (Davidse, 1973; Hammerschlag & Sisler, 1973; Styles & Garner, 1974; Seiler, 1975, 1976; Zutshi & Kaul, 1975). The anti-tumour drug, nocodazole, has recently been shown to induce mitotic arrest of cultured mammalian cells (DeBrabander *et al.*, 1975) and of cells of *D. discoideum* (Cappuccinelli *et al.*, 1979). To our knowledge, thiabendazole and cambendazole have not been used previously to induce mitotic arrest.

Present evidence indicates that the major genetic effect of benomyl and thiabendazole on *Aspergillus nidulans* is the induction of non-disjunction (Hastie, 1970; Kappas *et al.*, 1974; Kappas, 1978). While benomyl and MBC have been reported to induce point mutations in *Salmonella typhimurium* (Seiler, 1972; Kappas *et al.*, 1976), the induction of point mutations was not observed in *A. nidulans* (Hastie, 1970; Kappas *et al.*, 1974; Kappas, 1978), *Saccharomyces cerevisiae* (Siebert *et al.*, 1970) or mammalian cells (Seiler, 1975). Likewise, we have not detected changes in the frequency of developmental mutants in *D. discoideum* following treatment with any of the benzimidazole derivatives; their major genetic effect on *D. discoideum* appears to be the induction of non-disjunction.

The studies we report here using benzimidazole derivatives show that the increase in mitotic index is transitory and that the final block of cell division is in interphase. However, we disagree with the claim of Cappuccinelli *et al.* (1979), who only used nocodazole, that rapid deterioration of chromosomal structure occurred as the mitotic index decreased. Chromosomes and nuclei observed after the initial period of mitotic arrest appeared normal throughout these experiments although the nuclei varied in size. Our results suggest that benomyl (or MBC) has less effect than the other benzimidazole derivatives on spindle microtubules. While ben late did not block the cells in mitosis, it did induce haploidization of pre-existing diploids, inhibit cell division and induce a low frequency of chromosome doubling. The interference with cell division is reversible, particularly for ben late-treated cells, since the plating efficiency remained high. The low plating efficiency of cells treated with the other inhibitors is most likely due to the increase in aneuploidy and not to irreversible effects on microtubules.

In other systems, the primary effect of these benzimidazole derivatives appears to be on tubulin; several reports have described their binding to tubulin derived from both rat and bovine brain and also to fungal tubulin from *A. nidulans* (Hoebeke *et al.*, 1976; DeBrabander *et al.*, 1976; Friedman & Platzer, 1978; Davidse, 1975; Davidse & Flach, 1977). The toxicity of these compounds varies from species to species. For instance, the most effective inhibitor of the polymerization of bovine brain tubulin in *vitro* was nocodazole and the least effective was thiabendazole, yet both had similar effects on axenically grown *D. discoideum*. Likewise, the order of effectiveness of these benzimidazole derivatives for growth inhibition of the nematode *Caenorhabditis elegans* differed from that found for inhibition of the polymerization of bovine tubulin (Platzer *et al.*, 1977). The effectiveness of the benzimidazole derivatives on the induction of mitotic arrest also differs amongst species of cellular slime moulds.
Mitotic arrest in *D. discoideum* 405

While having little effect on mitotic arrest of *D. discoideum*, ben late induced a mitotic index of greater than 60% in *Polysphondylium pallidum* (Williams, 1980). However, even with *D. discoideum* we have found differences in the toxicity of ben late and nocodazole with amoebae grown in different ways. The effectiveness of these compounds presumably varied due to bacterial degradation or differences in the physiological state of the cells. The induction of isogenic diploids was dependent on the addition of yeast extract and bacteriological peptone in the ben late experiments using autoclaved bacteria, where bacterial degradation is excluded.

The benzimidazole derivatives provide three important advances in slime mould genetic analysis: haploidization, chromosome doubling and metaphase arrest. The duration of treatment and concentrations of benzimidazole derivatives used are critical. Diploid strains haploidize upon prolonged exposure to concentrations of the benzimidazole derivatives which do not prevent cell division of haploid strains. On the other hand, for successful metaphase arrest and chromosome doubling, the benzimidazole derivatives must be used for short periods at concentrations which prevent cell division. All four benzimidazole derivatives used were effective in the induction of haploidization of pre-existing diploids, an important step of the parasexual cycle. The procedures reported here make isolation of isogenic diploids routine. Although isogenic diploid strains of *D. discoideum* have been reported previously (Ross, 1960; Sussman, 1964; Wilson, 1953; Wilson & Ross, 1957), attempts to obtain isogenic diploids through controlled experiments have been unsuccessful in the past (Ross, 1960) except Sussman’s (1964) report of success using unaggregated amoebae. We have isolated isogenic diploids from a number of axenic and non-axenic strains using thiabendazole at 10 μg ml⁻¹. Such diploids will be of value, for instance, in studies determining the effect of ploidy on mutation (Williams, 1976) and on cell patterning during the developmental cycle (Stenhouse & Williams, unpublished results). Mitotic arrest in excess of 30% is now routine in axenic culture (Cappuccinelli et al., 1979; this report). Since nocodazole is relatively ineffective in the presence of live bacteria, its usefulness is diminished since many strains are unable to grow axenically. However, thiabendazole and cambendazole are equally effective on axenically and bacterially grown amoebae. Amoebae taken directly from clonal plates and treated for 2-5 h with thiabendazole at 10 μg ml⁻¹ routinely gave mitotic indices in excess of 30%, which provides enough mitoses for rapid karyotypic analysis. This procedure was effective on both haploid and diploid strains derived from NC4 and also on a number of other wild isolates of *D. discoideum* (Robson & Williams, 1980).

The high cost of colchicine and nocodazole precludes their routine use in solid media etc. By contrast, thiabendazole, cambendazole and ben late are all used commercially as fungicides or anthelmintics, so they are obtainable in large quantity for little cost. This report has been concerned primarily with the application of benzimidazole derivatives to genetic analysis in *D. discoideum*. However, they may prove valuable in studies involving microtubules other than those of the mitotic spindle. It is apparent that microtubules may have important roles in developmental processes such as cell wall formation in plants and algae (Dustin, 1978) and morphogenetic processes in *D. discoideum* (O'Day & Durston, 1978).

During the course of this investigation, D.L.W. was initially supported by grant DRG-206-F of the Damon Runyon-Walter Winchell Cancer Fund and subsequently by a National Institutes of Health Fellowship (1 F32 CA06162-01) from the National Cancer Institute. We thank William Bliss for the gift of thiabendazole and cambendazole. We thank Professor B. Gunning, Drs H. Marchant, E. Smith and K. Sripakrash for their comments on this manuscript.
