Immunochemical Characterization of Neisseria meningitidis Serotype Antigens by Immunodiffusion and SDS–Polyacrylamide Gel Electrophoresis Immunoperoxidase Techniques and the Distribution of Serotypes Among Cases and Carriers

By J. T. POOLMAN,* C. T. P. HOPMAN AND H. C. ZANEN
Laboratory of Hygiene, University of Amsterdam, Mauritskade 57, 1092 AD Amsterdam, The Netherlands
(Received 23 March 1979; revised 2 July 1979)

The chemical nature of the antigens of the meningococcal serotypes described by Frasch and colleagues was determined by a combination of immunodiffusion and the SDS–polyacrylamide gel electrophoresis immunoperoxidase technique (SGIP). It was confirmed that the serotype antigens of the outer membrane of serotypes 1, 2, 6, 9, 11 and 12 were proteins, whilst those of serotypes 4, 5 and 8 were lipopolysaccharides. Serotype 2 can now be divided into three related types, provisionally called 2a (originally serotype 2), 2b and 2c with the specific antigens being proteins having molecular weights of 41,000, 41,500 and 41,500, respectively. A total of 195 strains of meningococci isolated from patients and carriers in the Netherlands and 20 serogroup Y strains from patients in the U.S.A. were serotyped by means of immunodiffusion. Serotype 2a could be demonstrated in some strains belonging to the serogroups B (only those from carriers), C, W-135 and Y (only those from the U.S.A.). The W-135 strains isolated from patients in this series more often belonged to serotype 2a than did the W-135 strains from carriers. Serotype 2b was present in about half of the serogroup B and a few serogroup C strains isolated from patients with meningitis, but absent in serogroup B and C strains from carriers. Serotype 2c could only be demonstrated in serogroup Y strains, both from the Netherlands and the U.S.A. The other serotypes were found only sporadically.

INTRODUCTION

Neisseria meningitidis has been divided into nine serogroups [A, B, C, D, X, Y, Z, Z1 (29E) and W-135] with antisera raised to the capsular polysaccharides (Branham, 1953; Slaterus, 1961; Evans et al., 1968). The chemical structure of most of the group-specific polysaccharides has been elucidated (Jennings et al., 1977; Bhattacharjee et al., 1978). Further classification into serotypes is based on non-capsular antigens present in the outer membrane (Gold & Wyle, 1970; Frasch & Chapman, 1972a). Analysis of some of these serotype antigens by Frasch and Zollinger has shown them to be either proteins or lipopolysaccharides (Zollinger et al., 1972, 1974; Frasch & Gotschlich, 1974; Frasch et al., 1976; Zollinger & Mandrell, 1977).

To identify an organism accurately, to study the epidemiology and pathogenesis of the infection to which it gives rise and to develop an effective vaccine against that infection may depend upon knowledge of the detailed antigenic structure of the species. In addition, antiserum specific for particular antigens are required to allow reliance to be placed upon immunological methods of identification such as immunodiffusion, serum bactericidal activity
and agglutination (Gold & Wyle, 1970; Frasch & Chapman, 1972a, b; Jones & Tobin, 1976; Mandrell & Zollinger, 1977). It was to fulfil these requirements that the recently developed SDS–polyacrylamide gel electrophoresis immunoperoxidase technique (SGIP) of v. Raamsdonk et al. (1977) was applied to the analysis of the outer membranes of the meningococcus, the results of which form the basis of this communication. In addition, the distribution of the various meningococcal serotypes amongst a group of strains isolated from both patients and carriers is reported.

**METHODS**

_Bacterial strains._ The prototype meningococcal strains M1080 (serotype 1), B16B6 (serotype 2), M986 (serotype 2, 7), M1011 (serotype 2, 10), M981 (serotype 4), M992 (serotype 5), M990 (serotype 6), M978 (serotype 8), M982 (serotype 9), M136 (serotype 11) and S3032 (serotype 12) were obtained from Dr C. E. Frasch (Bureau of Biologics, Food and Drug Administration, Bethesda, Md, U.S.A.). These were used to study the nature of the antigen(s) in the various serotypes and to prepare type-specific antisera. The serotypes 3, 7 and 10 were not included in the series because the original prototype of serotype 3 was unsuitable for use and the antigens of serotypes 7 and 10, whenever present, occurred in conjunction with serotype 2 (Frasch & Chapman, 1972a, b). In addition, a total of 215 strains of _N. meningitidis_, 130 from cases of meningococcal disease and 85 from healthy carriers, were collected and examined with respect to their serogroup and serotype. With the exception of 20 serogroup Y strains isolated from cases of meningococcal disease and obtained from Dr H. A. Feldman (State University of New York, Upstate Medical Centre, Syracuse, N.Y., U.S.A.), every strain was isolated in the Netherlands from the blood, cerebrospinal fluid or nasopharynx of patients or carriers. The four strains studied in detail — 2996, 3006 (both serogroup B, serotype 2b), 2396 and 3459 (neither groupable, serotype 2c) — were isolated in the Netherlands from patients with meningitis.

_Cultural conditions and isolation of outer membrane complexes._ Organisms were cultured in Trypticase Soy Broth (Difco) and their outer membrane complexes (OMC) were isolated from overnight cultures as described by Poolman et al. (1978).

_Separation and chemical identification of OMC._ SDS–polyacrylamide gel electrophoretic (SDS–PAGE) separation of the components of OMC was carried out as described by Poolman et al., (1978). The following proteins (Boehringer) were used as molecular weight standards: cytochrome _c_ (mol. wt 12500); chymotrypsinogen _A_ (mol. wt 25000); aldolase (mol. wt 39500, polypeptide chains); ovalbumin (mol. wt 45000); catalase (mol. wt 60000, polypeptide chains); bovine albumin (mol. wt 67000).

_Gel immunoperoxidase technique (GIP)._ After SDS–PAGE, the separated OMC were analysed immunologically by the gel immunoperoxidase technique of v. Raamsdonk et al. (1977), incorporating a few modifications. The combination of SDS–PAGE and GIP has been called SGIP (SDS–polyacrylamide gel electrophoresis immunoperoxidase technique). The SDS gels were placed on metal holders covered with chromatographic paper, frozen in liquid nitrogen (keeping the metal holder in and the gel above the liquid nitrogen) and sliced longitudinally at — 35 °C with a cryostat microtome (Height 5030) into 50 μm slices (5 × 5 cm). The slices were freed from SDS and stored at — 20 °C in a mixture of ethanol/acetac acid (6:1, v/v). Before use, the slices were washed in PBS (2 mm-NaH₂PO₄, 8 mm-Na₂HPO₄ and 0.14 M-NaCl pH 7.2) to remove the ethanol/acetac acid mixture. The slices were spread and incubated on glass slides (10 × 10 cm) with rabbit antisera against meningococci (dilution series 1:2 to 1:2, 25, ± 15 μl per cm² gel) in a moist atmosphere at room temperature for 30 min and then at 4 °C overnight. After washing with PBS for 1 h the slices were incubated with goat anti-rabbit-IgG-peroxidase-labelled antiserum (Miles Laboratories, Elkhart, Ind., U.S.A.), specific for both light and heavy chains of rabbit IgG, (dilution 1:25) at room temperature for 2 h. Finally, the slices were washed with PBS at room temperature for 1 h and stained with 3-amino-9-ethylcarbazole (Sigma) for 15 to 30 min. The staining solution contained 0·05 M-acetate, 0·01% (v/v) H₂O₂, 5% _N,N_-dimethylformamide and 0·04% (w/v) 3-amino-9-ethylcarbazole pH 5·0. The staining solution was removed from the slices by washing with water. In turning red, the reacting antigens became visible. Control reactions were performed with goat anti-rabbit-IgG-peroxidase alone and in combination with pre-immunization rabbit serum.

**Micro-precipitation._** Ouchterlony immunoprecipitation was carried out on glass slides (5 × 5 cm) which were layered with 1·5% (w/v) agar Noble (Difco) in water. For serogrouping, immunodiffusion was carried out as described by Slaterus (1961). For serotyping, the antiserum wells were filled 6 h after the antigen wells; both the antigen and antiserum wells were filled twice. In all cases purified OMC were used as antigen. The slides were incubated in a moist atmosphere at room temperature for 24 to 48 h. After washing in PBS the slides were dried and stained with Coomassie brilliant blue (0·5%, w/v) in acetic acid:water:ethanol (1:4·5:4·5, by vol.) for 5 min.
Antisera. Antisera against serogroups were prepared according to Slaterus (1961) using the reference strains previously described (Poolman et al., 1978). Antisera to a serotype 1 strain (M266) and the prototype strains B16B6 (serotype 2), M1011 (serotype 2, 10), M992 (serotype 5), M990 (serotype 6) and M982 (serotype 9) were kindly supplied by Dr C. E. Frasch. In addition, antisera to the prototype strains obtained from Dr C. E. Frasch were raised in 2 month-old cross-bred white New Zealand rabbits (approx. 2.5 kg wt) according to the immunization schedule of Frasch & Chapman (1972a). When satisfactory precipitating titres were reached, the rabbits were bled by cardiac puncture. To obtain highly specific antisera, the serum from each immunized rabbit was then absorbed with an equivalent volume of packed meningococci to remove cross-reacting antibodies. After absorption at 37 °C for 4 h and then at 4 °C overnight, the bacteria were removed by centrifuging at 20000 g for 20 min at 4 °C. The following absorptions were found to be necessary: anti-serotype 1 with meningococci M992 and M978; anti-2a with M136, 2996 and 2396; anti-2b with M1011 and 2396; anti-2c with M1011 and 2996; anti-4 with M1011, M992 and S3032; anti-5 with M978 and M136; anti-6 with M1011, M136 and S3032; anti-8 with M981 and M992; anti-9 with M1080, M1011 and M136; anti-11 with M1011, M992 and M990; anti-12 with M981, M992 and M982. Before use the specificity of each absorbed antiserum was verified by Ouchterlony immunoprecipitation tests against each of the serotypes. Goat anti-rabbit-IgG-peroxidase-labelled antiserum was absorbed with a mixture of all prototype meningococci to remove any reactivity against the OMC. The antisera used in the experiments reported were prepared in our laboratory, unless stated otherwise.

RESULTS

Immunochrometry of serotype antigens, other than serotype 2

Outer membrane complexes from prototype strains 1, 4, 5, 6, 8, 9, 11 and 12 were analysed on two parallel gel slabs by SDS-PAGE. The remainder of these gels after longitudinal slicing were stained for proteins or lipopolysaccharides. The major outer membrane proteins (OMP) were located in the middle of the gel slab, indicative of a molecular weight between 25000 and 50000 (Fig. 1a), and the lipopolysaccharides were located at the anodic end (Fig. 1b). The position of the capsular polysaccharides, shown using group-specific antisera, was at the cathodic end of the gel slab (Poolman et al., 1978).

The treatment of the gel slices with any one of the specific serotype antisera, as judged by immunodiffusion, followed by development with GIP and staining with 3-amino-9-ethylcarbazole revealed extensive cross-reactivity (Fig. 1c, e, g). This cross-reactivity occurred not only with our own specific serotype antisera but also with those provided by Dr C. E. Frasch. However, further absorption with heterologous prototype serotype strains rendered the antisera specific as measured by the GIP technique (Fig. 1d, f, h). The specific antigens of serotypes 4, 5, 6, and 11 were identified as single entities by this procedure. However, despite repeated absorption of the antisera to serotypes 1, 8, 9 and 12 with heterologous prototype serotype strains, more than one antigen remained as revealed by the GIP technique (Fig. 1h). Further identification of the principal antigen responsible for type specificity in serotypes 1, 8 and 12 was obtained when these prototype serotypes were compared with strains isolated from patients and/or carriers and classified as of the same type by immunodiffusion yet different from each other with respect to their protein patterns. An example of this approach is given in Fig. 2 showing that the principal antigen responsible for specificity in serotype 12 is the protein of molecular weight 27000 rather than the additional one in the prototype serotype 12 whose molecular weight is 45000. Following this approach, the chemical nature of the only or principal antigen of the several serotypes, with the exception of serotype 9, was determined. Absolute characterization of the principal antigen of serotype 9 was not possible because no strain(s) immunologically identical to this prototype serotype was isolated from either patients or carriers.

The detailed chemical nature of the serotype antigens is given in Table 1.

**Immunochrometry of serotypes 2a, 2b and 2c**

Immunodiffusion failed to differentiate between the prototype serotype 2 strains B16B6 (serotype 2), M986 (serotype 2, 7) and M1011 (serotype 2, 10). We regarded these strains as belonging to one serotype, namely serotype 2, thereby following the approach of Frasch & Friedman (1977). Antisera raised against the prototype serotype 2 strains B16B6 and M1011, which after thorough absorption did not react with heterologous prototype strains, reacted with many strains of meningococci isolated in the Netherlands when tested by immunodiffusion. Some of these reacting strains showed immunological identity with the prototype serotype 2 strains, while others did not (Fig. 3). By raising antisera against the strains involved, these immunological differences could be characterized. After absorption, three different type-specific antisera, as determined by immunodiffusion, emerged (Fig. 3). The
serotypes identified with these antisera are provisionally designated serotype 2a (Frasch sero-
type 2, strains B16B6 and M1011), 2b (strains 2996 and 3006) and 2c (strains 2396 and 3459).

Incubation of OMC from these six strains separated by SDS–PAGE with antisera specific for
serotypes 2a, 2b and 2c followed by treatment with GIP and staining revealed the OMP
antigen(s) of the three serotypes to be distinct entities (Fig. 4b, c, d); all were proteins
(Fig. 4a).

Exposure of OMC from the prototype serotype 2 strains B16B6 and M1011 to type-
specific serotype 2 antiserum, produced in our own laboratory or received from Dr C. E.
Frasch, showed them to possess two common but type-specific OMP antigens of molecular
weights 41000 and 43500. However, exposure of the same two serotype OMC to anti-M1011
revealed the presence of a third OMP antigen of molecular weight 28000 in M1011 (Fig. 4b).
This additional antigen probably represents the serotype 10 antigen. The analysis of OMC
from freshly isolated strains of meningococci, identical on immunodiffusion to these two
prototype strains, provisionally designated serotype 2a, showed the OMP of molecular
weight 41000 to be the serotype 2a antigen.

Separation and immunological analysis of OMC from strains 2996 and 3006, designated
serotype 2b, showed them to possess a common but type-specific OMP antigen of molecular

NT, Non-typable; NG, non-groupable.

weight 41 500, with strain 3006, as revealed by immunological analysis with anti-3006 serum, possessing an additional OMP antigen of molecular weight 28000 (Fig. 4c).

Similar analysis of OMC from strains 2396 and 3459, designated serotype 2c, revealed one type-specific OMP antigen, of molecular weight 41 500 (Fig. 4d).

The detailed chemical nature of these serotype 2 subtypes is given in Table 1.

**Distribution of the characterized serotypes among patients and carriers**

Of 215 strains of meningococci, isolated either from cases of meningococcal disease or from healthy carriers, 98 could be assigned, by immunodiffusion of OMC, into one of the 11 serotypes. Of these 98 strains, 75 belonged to either serotype 2a (35 strains), 2b (24 strains) or 2c (16 strains). The majority of serotype 2a strains fell into serogroup W-135, particularly those isolated from patients, the other serotype 2a strains belonging to serogroups B, C and Y. Of the serotype 2b strains, which were all amongst the meningococci isolated from patients, 22/24 belonged to serogroup B. All the serotype 2c strains were associated with serogroup Y. Of the other serotypes represented in this series, serotype 8 was predominant (Table 2).

**DISCUSSION**

The analysis of the OMC of nine meningococcal serotypes described by Frasch et al. (1976) by both immunodiffusion and SGIP enabled the chemical nature of the principal antigen(s) to be identified. In addition, two new serotypes, immunologically related to serotype 2 (Frasch et al., 1976), were recognized.

The SGIP technique proved to be the more sensitive of the two methods of analysis since antisera exhibiting type-specific activity in immunodiffusion analysis gave cross-reactions when tested by the SGIP technique. However, the extensive absorption of such antisera with cross-reacting strains enabled antisera specific in the SGIP test to be developed. Using this approach, it was possible to demonstrate which proteins and lipopolysaccharides (LPS) within the outer membrane were the antigens responsible for serotype-specificity and that these antigens were stable when prepared as described, since different preparations gave identical results.
Frasch & Gotschlich (1974) showed the serotype 2 antigen, here renamed serotype 2a, to be an OMP of molecular weight 41000. Zollinger & Mandrell (1977) found that the prototype strains M981 (serotype 4), M992 (serotype 5) and M978 (serotype 8) stimulated the production of LPS-specific antibodies in the solid-phase radioimmunoassay. Both these findings have been confirmed by us.

The serotypes 2a, 2b and 2c formed the largest group of typable strains isolated from patients and, with the exception of serotype 2b, from carriers. Unlike Frasch & Chapman (1973), Jones & Tobin (1976) and Frasch (1977) we found no serotype 2a strains amongst those serogroup B meningococci isolated from cases of meningitis although, as also noted by Frasch & Chapman (1973), a few were found amongst carrier strains. However, just over half of the serogroup B strains isolated from cases of meningitis proved to be serotype 2b. This discrepancy may well be due to the recognition, reported here for the first time, of other serotype 2 strains.* The remainder of the serotype 2b strains, two in number, belonged to serogroup C. We, like Gold et al. (1971) and Munford et al. (1975), found some serotype 2a strains amongst the serogroup C strains. The vast majority of serogroup W-135 strains contained the serotype 2a antigen, the incidence being greater amongst the strains isolated from patients. Like Frasch & Friedman (1977) we found serotype 2a to be present amongst serogroup Y strains isolated from patients in the U.S.A. Interestingly, this serotype was absent from serogroup Y strains isolated in the Netherlands. Moreover, serotype 2c strains were more common amongst serogroup Y strains isolated in the U.S.A. than amongst those isolated in the Netherlands. These two findings might explain the higher attack rate of serogroup Y in the U.S.A. compared with Europe (Meningococcal Disease Surveillance Group, 1976; Communicable Disease Surveillance Centre, 1978). Investigation of the geographical distribution of serotypes 2a, 2b and 2c seems desirable.

On the basis of the findings discussed, serotypes 2a, 2b and 2c could be regarded as meningococcal virulence factors. It appears from our immunochemical investigations that a serotype 2a vaccine, although cross-reactive with serotypes 2b and 2c, will not be the most suitable for protection against serogroup B meningitis (Frasch, 1977; Zollinger et al., 1978). Perhaps, the serotype 2b antigen should be chosen for this purpose.

This investigation reveals that meningococcal OMP contain common immunodeterminants in addition to strain-specific components. Meningococci may contain more than one specific OMP, e.g. strains B16B6 (serotype 2a), M1011 (serotype 2a), S3032 (serotype 12) and 3006 (serotype 2b). With the exception of serotypes 2a, 2b and 2c, great heterogeneity exists amongst these strain-specific components. This suggests that OMP serotyping will be very broad and not suitable for the serological classification of meningococci. On the other hand, the heterogeneity amongst meningococcal OMP may be of assistance, in association with SDS-PAGE, in the elucidation of subtle or difficult epidemiological problems.

The ability of meningococcal LPS to induce type-specific antisera indicates the possibility for an LPS serotyping scheme. Possibly, the LPS show less heterogeneity than the OMP. Experiments to determine the value of meningococcal LPS for serological classification purposes have been carried out by Zollinger & Mandrell (1977). An LPS serotyping system is under development in our own laboratory.

* Note added in proof. The prototype serotype 2b and 2c strains 2996, 3006, 2396 and 3459 were protein serotyped and belonged to Frasch's serotype 2 by the bactericidal method and by co-agglutination (D. M. Jones, personal communication).

We are grateful to Dr C. E. Frasch for generously providing the prototype strains and some serotype reference antisera and to Dr H. A. Feldman for kindly sending us 20 serogroup Y strains from cases in the U.S.A. We thank Mrs S. S. Speet-Weinreich for her assistance with translating this article into English. This investigation was supported by a grant from the Preventie Fonds, researchnr. 28–310.
