(Received 9 May 1979; revised 28 August 1979)

DNA from the yeast *Kluyveromyces marxianus* was studied for its heterogeneity and the multiplicity of rRNA cistrons. These cistrons banded at a slightly different density from the bulk DNA in preparative CsCl or Hg²⁺-Cs₂SO₄ equilibrium density gradients. The reassociation kinetics of the bulk DNA showed that the repetitive fraction represented a small amount of the total cellular DNA (10%) and that the single copy fraction had a complexity of $6.3 \times 10^9$ daltons. Approximately 2-2% of the DNA hybridized to ³H-labelled rRNA at saturation. On the basis of the above genome size, the multiplicity of the rRNA cistrons was calculated to be about 70 per haploid nucleus.

**INTRODUCTION**

Information concerning the physical properties, multiplicity and organization of ribosomal RNA cistrons in yeasts has been mainly derived from studies with *Saccharomyces cerevisiae* (Cryer et al., 1973; Kaback et al., 1973). These investigations have revealed that there are approximately 100 to 140 cistrons per haploid genome (the haploid genome size is approximately $5 \times 10^9$ to $8 \times 10^9$ daltons), coding for 25, 18, 5S and 5S rRNA each. The 140 cistrons are not contiguous but 10 to 32 cistrons are grouped in clusters on more than one chromosome. These conclusions are based on the appearance of rDNA peaks on equilibrium density gradient centrifugation of DNA fragmented to defined molecular weight (Cramer et al., 1972). A *Saccharomyces cerevisiae* strain monosomic (2n-1) for chromosome I contains about 30% fewer genes coding for rRNA than the related diploid strain, indicating that about 70% of the rRNA cistrons are located on chromosome I (Oyen, 1973; Finkelstein *et al.*, 1972; Kaback *et al.*, 1973). In experiments with intact chromosomal DNA sedimented in sucrose gradients the rDNA was shown to be associated with two size classes of DNA molecules, one of which was linked to chromosome I (Finkelstein *et al.*, 1972).

*Kluyveromyces* is so closely related to *Saccharomyces* that Campbell (1972) has suggested the rejection of *Kluyveromyces* as a genus. However, studies of the nucleotide sequence homology (Bicknell & Douglas, 1970), genetic analysis (Tingle *et al.*, 1968) and the difference in the chromosome number (*K. lactis* has a haploid chromosome number of 9 compared to 15 for *S. cerevisiae*; Galeotti & Williams, 1978) justify the retention of *Kluyveromyces* as a separate genus. In view of these obvious similarities and differences we thought an investigation of the organization of rRNA cistrons in *Kluyveromyces* worthwhile. In this paper we report our results on the characterization of rRNA cistrons in *K. marxianus.*
METHODS

Organism, growth and DNA extraction. *Kluyveromyces marxianus* strain no. 712 CBS was maintained on malt agar slants at 25 °C. Yeast cells were scraped from malt agar slants (4 to 5 d-old), washed with distilled water by centrifugation, and inoculated in 1 l growth medium to give a density of about 1 x 10⁸ cells ml⁻¹. The growth medium, YPG (containing, per litre, 10 g yeast extract, 20 g peptone and 40 g glucose), was prepared in a 2 l Erlenmeyer flask and the culture was grown at 25 °C with forced aeration. After 48 h, the cells were harvested by centrifugation, washed with distilled water and frozen in liquid nitrogen. The frozen cell clumps were broken and ground to fine powder in liquid nitrogen with a Braun homogenizer. The broken cell powder was suspended in a lysis buffer (8 M-urea/0.24 M-sodium phosphate buffer pH 6.8/1.5 % (w/v) sodium dodecyl sulphate/10 mM-EDTA/1 M-sodium perchlorate) and deproteinized twice with chloroform/isoamyl alcohol (24:1, v/v). The DNA from the deproteinized supernatant was extracted on hydroxyapatite and further purified as described by Dutta & Ojha (1972).

Analytical equilibrium density gradient centrifugation. DNA (5 µg ml⁻¹) was prepared in either CsCl or Cs₂SO₄ solution, the latter containing HgCl₂ or AgNO₃ at heavy metal ion to DNAp ratios of 0-1 and 0-3, respectively, as described elsewhere (Ojha & Turian, 1977). The samples were centrifuged in an MSE analytical ultracentrifuge at 140000 g for 24 h at 25 °C. Ultraviolet photographs were traced using a Vernon photometric integrator recorder.

Preparative ultracentrifugation. CsCl, Hg⁺⁺- and Ag⁺-Cs₂SO₄ density gradient centrifugation was done as described earlier (Ojha & Turian, 1977). CsCl-actinomycin D gradient centrifugation was done according to Peacock et al. (1973). The actinomycin D complexed to DNA fractions was removed by extracting the DNA/CsCl/actinomycin D solution with propan-2-ol. This procedure was repeated twice. The Hg⁺⁺ or Ag⁺ ions complexed to DNA fractions were removed with 0.001 M-EDTA as described elsewhere (Ojha & Turian, 1977).

Individual fractions were denatured, neutralized, fixed on Millipore filters and hybridized with ³H-labelled rRNA from an aquatic fungus, *Allomyces arbuscula* (Ojha & Turian, 1977).

Thermal denaturation. The procedure followed has been described previously (Ojha, 1978). The denaturation profile was analysed by the differential melting curve and the probability plot method of Knittel et al. (1968).

Reassociation kinetics. The fragmentation of the DNA samples, evaluation of the fragment length, denaturation and the procedure of reassociation have been described elsewhere (Ojha et al., 1977).

A minimum of 1 unit of absorbance of the fragmented DNA was sealed in the reaction vials and incubated at 60 °C. After incubation to the desired Cot value (Cot is the concentration of nucleotide in mol S⁻¹ l⁻¹; Britten & Kohne, 1968), further reassociation was terminated by quickly plunging the vials into ice. The reassociated DNA was differentiated on hydroxyapatite columns as described elsewhere (Dutta & Ojha, 1972).

Isolation of ³H-labelled rRNA from *K. marxianus*. YPG medium (500 ml) containing 500 µCi (18.5 MBq) [³H]uridine was inoculated with 7 d-old cells grown on grape juice slants and incubated with forced aeration at 25 °C. After 24 h growth, 100 times the quantity of unlabelled uridine was added and the culture was allowed to grow for another 5 h. The ribosomes and rRNA were isolated according to Rubin (1975). The rRNA subunits (25+18S) were purified by polyacrylamide-agarose (acylamide, 2-4 %, w/v; agarose, 0-5 %, w/v) electrophoresis and rRNA species were recovered as described by Rubin (1975).

RESULTS

Satellite DNAs

The presence of satellite DNAs was investigated by analytical equilibrium centrifugation in CsCl, Hg⁺⁺- or Ag⁺-Cs₂SO₄ and by analysis of the melting curve by the differential or probability plot method of Knittel et al. (1968). The equilibrium density gradient centrifugations did not reveal the presence of distinct satellites. However, the probability plot of the denaturation data showed the presence of two populations of molecules differing in their G+C values. The major and minor components had 43 and 23 mol % G+C, respectively.

Frequency of ribosomal RNA genes

Saturation hybridization. The number of ribosomal RNA gene copies in the *K. marxianus* genome was estimated by hybridizing denatured DNA immobilized on nitrocellulose filters...
Fig. 1. Saturation hybridization of *K. marxianus*, *S. cerevisiae* and *N. crassa* DNA with \(^3\)H-labelled rRNA (25+18S) from *K. marxianus*. (a) Respective DNAs were fixed on nitrocellulose filters and hybridized with increasing concentrations of rRNA (sp. act. 7000 c.p.m. \(\mu g^{-1}\)) under the conditions described in Methods. (b) Double reciprocal plots of the saturation data. ○, *K. marxianus*; ■, *S. cerevisiae*; △, *N. crassa*.

Fig. 2. Reassociation kinetics of *K. marxianus* DNA. DNA was sheared (average fragment length 1000 base pairs), denatured and reassociated as indicated in Methods. DNA concentration, phosphate buffer molarities and temperatures of incubation were as follows: from \(C_{ot}10^{-3}\) to \(10^{-4} - 40 \mu g\) ml\(^{-1}\), 0·12 M and 60 °C; from \(C_{ot}10^8\) to \(10^9 - 850 \mu g\) ml\(^{-1}\), 0·14 M and 60 °C; from \(C_{ot}10^9\) to \(10^{10} - 1150 \mu g\) ml\(^{-1}\), 0·48 M and 66 °C. The reassociated fractions were separated from the unreassociated DNA by hydroxyapatite chromatography as described by Dutta & Ojha (1972). ○, Experimental results; ●, theoretical curve of possible single copy sequences.

with increasing concentrations of combined \(^3\)H-labelled (25+18S) homologous rRNA (Fig. 1). The plateau value obtained revealed that 1·6% of the DNA was complementary to rRNA at saturation. The saturation value of 2·2% was obtained by the double reciprocal transformation (Bishop, 1972) of the above data and represents the percentage hybridization at infinite concentration of the rRNA. As a control, heterologous hybridization was done with *S. cerevisiae* and *Neurospora crassa* DNA; the saturation values obtained were 2·4 and 1%, respectively (Fig. 1).

**Genome size.** The genome size was determined from the rate of reassociation of the total cellular DNA. From the reassociation kinetics of total cellular DNA sheared to an average length of 1000 base pairs (Fig. 2), the following results were obtained. (1) Repetitive sequences represented a very small amount of the total DNA; approximately 10% of the DNA reassociated faster than expected from single copy sequences. (2) The slowly re-
associating component accounted for 90% of the total DNA and appeared to be kinetically homogeneous. (3) The $C_{ot}$ of the slowly reassociating component was 10, which is about 2.5 times that of *Escherichia coli* sheared to equivalent fragment length (Ojha *et al.*, 1977) and reassociated under comparable conditions (not shown in Fig. 2). Considering the genome size of *E. coli* to be $2.8 \times 10^9$ daltons the molecular mass of *K. marxianus* DNA was calculated to be approximately $6.3 \times 10^9$ daltons.

**Separation of the rRNA cistrons**

The total cellular DNA was fractionated on a preparative neutral CsCl gradient and the individual fractions were hybridized with $^3$H-labelled rRNA from *Allomyces arbuscula*. The results indicated that most of the cistrons coding for rRNA banded at a slightly lower density than the main peak DNA where very little hybridization occurred (Fig. 3).
The banding pattern of rRNA cistrons in CsCl–actinomycin D and Ag\textsuperscript{+}–Cs\textsubscript{2}SO\textsubscript{4} gradients in cacodylate buffer pH 7–0 corresponded to the main peak DNA. When bulk DNA was complexed with Hg\textsuperscript{2+} in borate buffer pH 9–2 in Cs\textsubscript{2}SO\textsubscript{4}, centrifuged to equilibrium and individual fractions hybridized with \textsuperscript{3}H-labelled rRNA, the cistrons were found to band in the heavier regions of the main band (Fig. 4). However, the cistrons did not resolve into distinct satellites.

**DISCUSSION**

In *S. cerevisiae* and *S. carlsbergensis*, cistrons coding for rRNA appear as distinct satellites—the Y satellites—in analytical equilibrium density gradient centrifugations in CsCl, Hg\textsuperscript{2+}– or Ag\textsuperscript{+}–Cs\textsubscript{2}SO\textsubscript{4} (Corneo et al., 1966; Cramer et al., 1972; De Kloet, 1970; Karijord & Øyen, 1975). In contrast, we have not found any satellite with *K. marxianus* DNA under similar conditions of centrifugation.

Saturation hybridization experiments demonstrated that 2–2.2% of the DNA codes for 25+18s rRNA in *K. marxianus*. This represents 1.4×10\textsuperscript{8} daltons of coding sequences considering the genome size of *K. marxianus* to be 6.3×10\textsuperscript{9} daltons (see below). The combined molecular mass of 25+18s rRNA in yeast has been shown to be 2×10\textsuperscript{8} daltons (Udem & Warner, 1972). Therefore, 1.4×10\textsuperscript{8} daltons of DNA should represent approximately 70 cistrons. This number is half of the 140 cistrons reported for *S. cerevisiae* (Schweizer et al., 1969). The control saturation hybridization values obtained with heterologous DNA from *S. cerevisiae* (2.4%) and *Neurospora crassa* (1%) correspond to the published results (De Kloet, 1970; Chattopadhyay et al., 1972) and attest to the validity of our method. The difference in chromosome number between *S. cerevisiae* (17) and *K. marxianus* (9) should not account for this difference, since *Neurospora crassa* with 7 chromosomes has 100 cistrons per nucleus (Chattopadhyay et al., 1972). Furthermore, an increase in the level of ploidy does not lead to any increase in the number of cistrons per nucleus in *Physarum polycephalum* (Hall et al., 1975).

The kinetics of reassociation indicated that repetitive sequences represent about 10% of the total DNA and that the *C_{af}t_{4}* of the possible single copy sequence is 10. This is about 2–5 times that of *E. coli* measured under comparable conditions. Physical measurements of *E. coli* have given a genome size of 2.8×10\textsuperscript{9} daltons (Cairns, 1963), and so we calculate the genome size of *K. marxianus* to be approximately 6.3×10\textsuperscript{9} daltons, assuming that the non-repeated portion represents approximately 90% of the total genome (2.8×10\textsuperscript{9} × 2.5×0.9). This is in close agreement with the value published by Christiansen et al. (1971) for *K. lactis*.

CsCl gradient centrifugation results have shown that rDNA in *K. marxianus* is lighter than the main peak DNA, in contrast to *S. cerevisiae* where it is associated with a heavy satellite DNA (Schweizer et al., 1969). However, we found no evidence of a light satellite peak with *K. marxianus*. The specificity of actinomycin D binding to G+C regions of the DNA has been used to separate the rRNA cistrons in higher organisms (Peacock et al., 1973). In our experiments with *K. marxianus* DNA the rRNA cistrons did not react differentially with actinomycin D and so did not appear as a satellite. However, separation was achieved with Hg\textsuperscript{2+}–Cs\textsubscript{2}SO\textsubscript{4} gradients where rRNA cistrons appeared in the heavier side of the gradient. The actinomycin D and Hg\textsuperscript{2+} binding experiments suggest that the rRNA cistrons in *K. marxianus* are A+T rich as in *S. cerevisiae* and *A. arbuscula* (Ojha & Turian, 1977).

The authors are grateful to Professor G. Turian, Department of Plant Biology, University of Geneva, for laboratory facilities and constant encouragement, Dr J. P. Tessier, Department of Medical Biophysics, University of Claude Bernard, Lyon, for analytical centri-
fugation, Miss A. Cattaneo for technical assistance and Mrs B. Duchoud for secretarial help.
