Pentose Phosphate-dependent Fixation of Formaldehyde by Methanol-grown *Hansenula polymorpha* and *Candida boidinii*

By MARY L. O'CONNOR† AND J. R. QUAYLE∗

Department of Microbiology, The University, Sheffield S10 2TN

(Received 3 April 1980)

A method has been developed for the continuous spectrophotometric assay of dihydroxyacetone synthase present in methanol-grown yeasts. This enzyme catalyses the condensation of formaldehyde with a pentose phosphate (most probably xylulose 5-phosphate) to give dihydroxyacetone and glyceraldehyde 3-phosphate. The assay is based on the NADH- and ATP-linked formation of L-glycerol 3-phosphate from dihydroxyacetone via the added coupling enzymes glycerol kinase and glycerol-3-phosphate dehydrogenase, and the reaction was followed by the decrease in absorbance at 340 nm. Using this assay, the pH optimum of the dihydroxyacetone synthase was shown to be 7.4 to 7.6. The enzyme, which catalyses a transketolase-like reaction, is a separate enzyme from the classical transketolase because their specific activities varied independently in *Candida boidinii* and *Hansenula polymorpha* grown on different substrates and the two enzyme activities could be separated by ion-exchange chromatography.

INTRODUCTION

Recent studies (van Dijken *et al.*, 1978; Babel & Löffhagen, 1979; O'Connor & Quayle, 1979; Kato *et al.*, 1979; Waites & Quayle, 1980; Lindley *et al.*, 1980) have shown that a novel pentose phosphate cycle of formaldehyde fixation operates in methanol-utilizing yeasts. One of the key steps of this cycle is the condensation of xylulose 5-phosphate with formaldehyde to give dihydroxyacetone (DHA) and glyceraldehyde 3-phosphate (Kato *et al.*, 1979; Waites & Quayle, 1980). The enzyme(s) which is presumably responsible for catalysing this reaction has been given the trivial name ‘DHA synthase’ and it seems likely that it is a type of transketolase in which formaldehyde acts as the aldehyde acceptor for transfer of a glycolaldehyde fragment from carbon atoms 1 and 2 of the xylulose 5-phosphate. It may be recalled that Dickens & Williamson (1958) discovered that transketolase from *Saccharomyces cerevisiae* catalysed a slow condensation of hydroxypyruvate with formaldehyde to give DHA and carbon dioxide.

Now that the existence of the DHA synthase reaction in extracts of methanol-grown yeasts has clearly been established it is of interest to determine the nature of the enzyme(s) responsible and to establish its identity or otherwise with the transketolase present in yeasts grown on substrates other than methanol. The work described in the present paper is directed to this problem in regard to the methylotrophic yeasts, *Candida boidinii* and *Hansenula polymorpha*.

METHODS

Abbreviations. DHA, dihydroxyacetone; DHAP, dihydroxyacetone-3-phosphate; GAP, glyceraldehyde-3-phosphate; XuMP, xylulose-5-phosphate.

Media and growth conditions. Organisms were grown in shake flasks at 37 °C (for H. polymorpha) or 30 °C (for C. boidinii) in the mineral salts medium used by van Dijken et al. (1976). Filter-sterilized methanol (0.5%, v/v), ethanol (0.2%, w/v) or dihydroxyacetone (0.1%, w/v) and autoclaved glucose or glycerol (0.2%, w/v) were used as carbon and energy sources. For all enzyme studies, cultures were harvested in late-exponential phase.

Preparation of extracts. Cell-free extracts were prepared by ultrasonication (MSE model 150 W) for 7 × 1 min (H. polymorpha) or 5 × 1 min (C. boidinii) at 1 min intervals in 4 vol. 20 mM-KH₂PO₄/NaOH buffer pH 7.1 (for enzyme assays) or 20 mM-glycylglycine buffer pH 7.6 containing 5 mM-MgCl₂ (for purification of C. boidinii DHA synthase). The supernatant obtained after centrifugation at 38000 g for 20 min was used for all enzyme studies.

Enzyme assays. All assays were carried out in 1 ml total volume at 37 °C (H. polymorpha) or 30 °C (C. boidinii) using a Pye Unicam SP1800 double-beam recording spectrophotometer.

Transketolase (EC 2.2.1.1) was assayed as described by de la Haba et al. (1955) using a commercial mixture of triosephosphate isomerase and glycerol-3-phosphate dehydrogenase (Boehringer).

Dihydroxyacetone synthase was assayed by two methods. (1) Based on triose phosphate formation. The complete reaction mixture contained: glycylglycine buffer pH 7-6, 50 mM; MgCl₂, 2 mM; NADH, 0.15 mM; thiamin pyrophosphate, 0.005% (w/v); triosephosphate isomerase (EC 5.3.1.1), 6 units; glyceraldehyde-3-phosphate dehydrogenase (EC 1.1.1.8) (from rabbit muscle), 0.5 unit. After incubation of cell-free extracts with the above mixture for 5 min to assess NADH oxidase activity and to allow initial rates to level off, XuMP was added to a final concentration of 2.5 mM and incubation was continued for an additional 5 min to allow initial high rates to level off. The synthase reaction was then started by the addition of formaldehyde to pH 7.6 containing 5 mM-MgCl₂ (for purification of C. boidinii DHA synthase). The supernatant obtained after centrifugation at 38000 g for 20 min was used for all enzyme studies.

Enzyme assays. All assays were carried out in 1 ml total volume at 37 °C (H. polymorpha) or 30 °C (C. boidinii) using a Pye Unicam SP1800 double-beam recording spectrophotometer.

Transketolase (EC 2.2.1.1) was assayed as described by de la Haba et al. (1955) using a commercial mixture of triosephosphate isomerase and glycerol-3-phosphate dehydrogenase (Boehringer).

Dihydroxyacetone synthase was assayed by two methods. (1) Based on triose phosphate formation. The complete reaction mixture contained: glycylglycine buffer pH 7-6, 50 mM; MgCl₂, 2 mM; NADH, 0.15 mM; thiamin pyrophosphate, 0.005% (w/v); triosephosphate isomerase (EC 5.3.1.1), 6 units; glyceraldehyde-3-phosphate dehydrogenase (EC 1.1.1.8) (from rabbit muscle), 0.5 unit. After incubation of cell-free extracts with the above mixture for 5 min to assess NADH oxidase activity and to allow initial rates to level off, XuMP was added to a final concentration of 2.5 mM and incubation was continued for an additional 5 min to allow initial high rates to level off. The synthase reaction was then started by the addition of formaldehyde to a final concentration of 1 mM. Since crude extracts exhibited a XuMP-dependent formaldehyde reduction, all assays were also performed with the opposite order of addition of formaldehyde and XuMP, i.e. formaldehyde first, followed by XuMP.

(2) Based on dihydroxyacetone formation. The complete reaction mixture contained: glycylglycine buffer pH 7-6, 50 mM; MgCl₂, 2 mM; NADH, 0.15 mM; thiamin pyrophosphate, 0.005% (w/v); ATP, 1 mM; glyceraldehyde-3-phosphate dehydrogenase (EC 1.1.1.8) (from Candida mycoderma), 0.4 unit; glyceraldehyde-3-phosphate dehydrogenase, 0.4 unit. The assay was carried out as for assay 1, above.

Partial purification of DHA synthase and transketolase from H. polymorpha and C. boidinii. Step 1: ammonium sulphate treatment. The crude extracts were taken to 50% saturation with (NH₄)₂SO₄ by the slow addition of solid (NH₄)₂SO₄ at 0 °C. The table of Dawson et al. (1969) was used to compute the amount required. After equilibration at 0 °C for 1 h, the mixture was centrifuged (38000 g, 10 min, 0 °C) and the supernatant was made up to 70% saturation with (NH₄)₂SO₄. This mixture was equilibrated and centrifuged as above and the fraction precipitating between 50 and 70% saturation was dissolved in 20 mM-glycylglycine buffer pH 7-6 containing 5 mM-MgCl₂ and used for DEAE-cellulose chromatography.

Step 2: DEAE-cellulose chromatography. The fractions obtained from (NH₄)₂SO₄ treatment were desalted on a Sephadex G-25 column and applied to columns (1.5 × 4 cm) of DEAE-cellulose (Whatman DE52) previously equilibrated with 20 mM-glycylglycine buffer pH 7-6 containing 5 mM-MgCl₂ and 20% (w/v) glycerol. The proteins were then eluted with a linear NaCl gradient (0 to 0.3 M made up in 400 ml of the column buffer) and 5 ml fractions were collected.

Analytical methods and chemicals. Protein was estimated by the Lowry method using bovine serum albumin as standard. Biochemicals and enzymes were obtained from Boehringer except for the following: dl-glyceroldehyde and DHA from BDH; ribose 5-phosphate, ribulose 5-phosphate and XuMP from Sigma. Formaldehyde was prepared from an aqueous suspension of paraformaldehyde by heating in a closed vessel overnight.

RESULTS

Detection and assay of dihydroxyacetone synthase

The detection and assay of the DHA synthase reaction:

\[ \text{HCHO} + \text{XuMP} \rightarrow \text{DHA} + \text{GAP} \]  \hspace{1cm} (1)

can be approached in several ways. The disappearance of formaldehyde or appearance of
DHA can be followed colorimetrically (Kato et al., 1979; Waites & Quayle, 1980), but both methods of estimation lead to discontinuous enzyme assays which are inconvenient for multiple use. Use of continuous spectrophotometric assays of product formation catalysed by crude extracts of these methanol-grown yeasts is fraught with difficulties for the following reasons. Firstly, crude extracts are rich in transketolase and pentose phosphate epimerases and isomerases and these combined activities result in the formation of GAP which is independent of formaldehyde. Secondly, crude extracts contain high levels of NADH-linked formaldehyde and DHA reductase activities which are independent of XuMP. The formaldehyde reductase activity may possibly be due to the activity of ethanol dehydrogenase, and the physiological role of the DHA reductase is probably that of a glycerol dehydrogenase. Hence any coupled assay which involves dehydrogenation of reduced nicotinamide nucleotides can be expected to involve high blank rates.

An attempt was made to detect formaldehyde- and XuMP-dependent formation of GAP by coupling its formation to the action of triosephosphate isomerase and glycerol-3-phosphate dehydrogenase (assay 1 in Methods).

\[
\text{GAP} \leftrightarrow \text{DHAP} \tag{2}
\]

\[
\text{DHAP} + \text{NADH} \rightarrow \text{l-Glycerol 3-phosphate} + \text{NAD} \tag{3}
\]

High blank rates were observed and no reproducible and stable rate of NADH oxidation which was dependent on the simultaneous presence of formaldehyde and XuMP was detected.

Positive and more reproducible results were, however, obtained by measuring DHA formation by assay 2 (see Methods). This assay involved coupling DHA formation to the action of the glycerol kinase of \textit{C. mycoderma} which catalyses the phosphorylation of not only glycerol but also DHA (Hers, 1962; Gancedo et al., 1968).

\[
\text{DHA} + \text{ATP} \rightarrow \text{DHAP} + \text{ADP} \tag{4}
\]

The DHAP formation was then followed by NADH oxidation via reaction (3). Under these conditions, in crude extracts of both yeasts, the rates of NADH oxidation observed in the presence of formaldehyde or XuMP singly were increased approximately twofold (at least) when both substrates were present together (Fig. 1). This activity, dependent on the simultaneous presence of both substrates, was also dependent on the presence of ATP and the coupling enzymes glycerol-3-phosphate dehydrogenase and glycerol kinase. We therefore ascribe this activity to the presence of enzyme(s) catalysing reaction (1), i.e. 'DHA synthase'.

The calculation of DHA synthase activity from the recorder traces may best be illustrated by an actual example worked out from Fig. 1(a, b). From Fig. 1(a) the final steady rates of change of \(A_{540} \text{ min}^{-1}\) were: initial, 0.025; after addition of XuMP, 0.030; after addition of formaldehyde, 0.070. Thus, the increment of rate decrease of \(A_{540}\) consequent upon addition of formaldehyde was 0.040 min\(^{-1}\). This rate, however, contained within it a contribution from formaldehyde reductase activity, which was corrected for by reference to Fig. 1(b). This latter measurement gave final steady rates of change of \(A_{540} \text{ min}^{-1}\) as follows: initial, 0.025; after addition of formaldehyde, 0.035; after addition of XuMP, 0.06. Therefore, the rate of decrease of \(A_{540} \text{ min}^{-1}\) due to formaldehyde reductase activity was 0.035 - 0.025 = 0.010. Hence, the fully corrected rate in Fig. 1(a) was 0.040 - 0.010 = 0.030 \(\Delta A_{540} \text{ min}^{-1}\). By a similar process, a fully corrected rate in Fig. 1(b) could be calculated, using a correction from Fig. 1(a) for the XuMP-dependent (but formaldehyde-independent) rate of change of \(A_{540}\) viz. 0.030 - 0.025 = 0.005. This then gave a fully corrected rate for Fig. 1(b) of 0.060 - 0.035 - 0.005 = 0.020 \(\Delta A_{540} \text{ min}^{-1}\). For reasons that are not at present understood, higher activities were generally obtained when XuMP was added before formaldehyde, as in Fig. 1(a).

Using this assay, specific activities in crude extracts prepared from methanol-grown cells...

proved variable in both organisms, ranging up to 0.10 and 0.22 μmol NADH oxidized min⁻¹ (mg protein)⁻¹ in H. polymorpha and C. boidinii, respectively. The many interfering activities present in crude extracts render the assay quantitatively unreliable under such conditions and it is preferable in such circumstances to use the discontinuous procedure developed by Waites & Quayle (1980). However, in later stages of enzyme purification, when interfering activities have been removed, the continuous spectrophotometric assay becomes increasingly useful.

The specific activity of DHA synthase was measured in crude extracts of C. boidinii and H. polymorpha, grown on various substrates, by direct spectrophotometric assay method 2 and compared with that of transketolase (Table 1). DHA synthase was only detected when the organisms were grown on methanol, whereas transketolase was detected after growth on all substrates tested. This suggests that the two activities are due to two different enzymes.
Table 2. Substrate specificity of DHA synthase from H. polymorpha and C. boidinii

All substrates were tested by the continuous spectrophotometric assay as described in Fig. 1. Substrates were used at a final concentration of 2-5 mM (except for ribose 5-phosphate which was at 5 mM). The specific activities of the enzyme preparations with XuMP were 0.08 μmol min⁻¹ (mg protein)⁻¹ for H. polymorpha and 0.17 μmol min⁻¹ (mg protein)⁻¹ for C. boidinii. The preparations used were 50 to 70 % saturation ammonium sulphate fractions, as described in Methods.

NT, This could not be tested in H. polymorpha preparations due to high transketolase activities.

Table 3. Partial purification of DHA synthase and transketolase from methanol-grown C. boidinii

The crude extract was prepared from 5 g cell paste suspended in 20 ml 20 mM-glycylglycine buffer pH 7.6 containing 5 mM-MgCl₂. DHA synthase was assayed using a mixture of ribose 5-phosphate and pentose phosphate interconverting enzymes, see Table 2. Activities are expressed as μmol min⁻¹, and specific activities as μmol min⁻¹ (mg protein)⁻¹.

Partial purification of DHA synthase

The DHA synthase activity in extracts of H. polymorpha or C. boidinii could be precipitated between 50 and 70 % saturation with ammonium sulphate and testing of this fraction showed that the best substrate for the reaction was XuMP (Table 2). Consistent with this was the finding that with the extract from C. boidinii, the activity of XuMP could be mimicked by the addition of ribose 5-phosphate only in the presence of added ribose-5-phosphate isomerase and ribulose-5-phosphate 3-epimerase. This test could not be repeated with the preparation from H. polymorpha because of the higher interfering levels of transketolase which were present.

The pH optimum of the DHA synthase in C. boidinii was 7.4 to 7.6; the enzyme showed markedly less activity in Tris buffer than in phosphate or glycylglycine. Similar results were obtained with H. polymorpha.
Fig. 2. Separation of DHA synthase and transketolase by chromatography on DEAE-cellulose using a linear gradient of NaCl. Details are given in Methods. Samples (50 μl) of fractions were assayed for enzyme activity [results are expressed as nmol min⁻¹ (ml sample)⁻¹]: ○, DHA synthase; ●, transketolase. Protein was monitored by measurement of absorbance at 280 nm (--.--).

Difficulties were encountered in the further purification of DHA synthase from either *H. polymorpha* or *C. boidinii* owing to the instability of the enzymes. The enzyme from *C. boidinii* was, however, more stable than that from *H. polymorpha* and was subjected to fractionation with ammonium sulphate, desalting on a column of Sephadex G-25 followed by chromatography on a column of DEAE-cellulose, using a gradient of NaCl (see Methods). It was found advantageous to include 20% (w/v) glycerol in the column buffer and eluting buffer as this stabilized the DHA synthase to some extent. With this procedure a partial purification of DHA synthase was effected in which the DHA synthase and transketolase activities were purified to different extents (Table 3). During the DEAE-cellulose chromatography the DHA synthase and transketolase activities clearly separated into two peaks, showing that they were indeed due to different enzymes (Fig. 2). The purified DHA synthase was very unstable at this stage, losing all activity within 12 h at 4 °C.

**DISCUSSION**

The studies described by Kato et al. (1979), Waites & Quayle (1980) and by the present authors are together consistent with the presence of an enzyme catalysing reaction (1) in extracts of methanol-grown *Kloeckera 2201*, *C. boidinii CBS 5777* and *H. polymorpha CBS 4732*. Due to the many interfering activities present in crude extracts of such yeasts, the unequivocal and accurate assay of the enzyme in crude extracts can present considerable problems which have been exposed in the present paper and the previous paper by Waites & Quayle (1980). Bearing these difficulties in mind it should be noted that the specific activities of DHA synthase recorded by three groups of authors in the three different yeasts grown on methanol fall within the range 80 to 220 nmol min⁻¹ (mg protein)⁻¹. Waites & Quayle (1980) have estimated that a specific activity of 150 nmol min⁻¹ (mg protein)⁻¹ for this enzyme would be sufficient to support a mean generation time on methanol of 6.4 h (assuming the carbon and protein contents of the cellular dry weight are each 50% and that all the carbon of the cell is incorporated via DHA).

The fact that DHA synthase is only synthesized during growth on methanol while the classical transketolase is synthesized to high levels during growth on all substrates tested indicates that the two activities are due to different enzymes. This is confirmed in the present study by the clear separation of these two activities by ion-exchange chromatography. Further study of the properties of the purified DHA synthase and detailed comparison of it with transketolase have, so far, been hampered by its apparent instability.
Formaldehyde fixation by C₁-utilizing yeasts

We acknowledge helpful discussion with Dr J. P. van Dijken, Dr W. Harder, Dr A. J. Beardsmore and Dr M. J. Waites and we are grateful for financial support from the Leverhulme Trust (to M. L. O’C) and from the Science Research Council by way of grant no. GR/A/65966.
