Effect of Methyl Methanesulphonate on the Nucleoid Structure of Escherichia coli

By Ivar Lossius, Per Gørán Krüger and Kjell Kleppe

Department of Biochemistry and Department of Anatomy, University of Bergen, Bergen, Norway

(Received 3 April 1980; revised 13 October 1980)

Incubation of a strain of Escherichia coli K12 with 25 mM-methyl methanesulphonate (MMS) for 1 h changed the sedimentation coefficient of the nucleoids from 1600S to 850S. When isolated nucleoids were treated with MMS under identical conditions in vitro there was no change in the sedimentation coefficient. Alkaline sucrose-gradient centrifugation of DNA from cells treated with 25 mM-MMS for 1 h indicated that there were approximately 100 breaks plus apurinic sites per chromosome. Titration with ethidium bromide of nucleoids from MMS-treated cells showed that almost all supercoiling had been lost, suggesting that the breaks plus apurinic sites consisted mostly of breaks. Further experiments showed that the apurinic sites were probably created by non-enzymic depurination and that little non-enzymic strand breakage had occurred. The depurinated sites thus created could then serve as substrates for the apurinic-specific endonucleases of the cell, with the result that strand breakage occurred. MMS treatment did not cause any changes in the DNA : RNA ratio of the nucleoids. Removal of MMS followed by a period of incubation resulted in a decrease in the number of breaks plus apurinic sites and an increase in the sedimentation coefficient of the nucleoids. After 2 h incubation in MMS-free medium the sedimentation coefficient of the nucleoids from MMS-treated cells was the same as that of the control; the supercoiling was also partially restored.

The effect of MMS on two MMS-sensitive mutants of E. coli, one a polA and the other a recA mutant, was also studied. In both cases MMS caused complete collapse of the nucleoid structure.

INTRODUCTION

In bacteria the chromosome exists as a compact, supercoiled structure often termed a nucleoid (Pettijohn, 1976; Kleppe et al., 1979). The nucleoid can be isolated free from cell envelope components and its properties studied in vitro (Stonington & Pettijohn, 1971; Pettijohn et al., 1973; Drlica & Worcel, 1975; Kavenoff & Bowen, 1976; Hecht et al., 1977). The nucleoid structure is affected by the physiological conditions of the cell and by chemicals (Worcel & Burgi, 1972; Dworsky & Schaechter, 1973; Korch et al., 1976; Lydersen & Pettijohn, 1977; Drlica & Snyder, 1978; Kleppe & Lossius, 1978; Øvrebo & Korch, 1978). In order to gain a better understanding of the mechanism of action of mutagenic compounds as well as the structure of the nucleoid both in vivo and in vitro, we have studied the changes that take place in the nucleoid structure when cells are treated with various mutagenic agents (Kleppe & Lossius, 1978). The present work deals with the effect of the monofunctional alkylating agent methyl methanesulphonate (MMS) on a mutant of Escherichia coli K12 that has been used previously in studies of the nucleoid, and on two MMS-sensitive strains.

The main effect of MMS is to methylate the purine residues in DNA and RNA and amino acid residues in proteins (Lawley, 1966, 1974; Rhæse & Freese, 1969; Prakash & Strauss,
1970; Singer, 1975, 1977). The methylated bases in DNA are only slowly excised by repair enzymes. Non-enzymic depurination of methylated bases as well as specific strand cleavage are also known to occur (Singer, 1975). Several mutants of E. coli, such as those with mutations in polA, recA, recB and recC, are particularly sensitive to MMS (Howard-Flanders & Boyce, 1966; Gross & Gross, 1969; Bridges et al., 1973; Thielmann et al., 1975). These mutants are also sensitive to u.v. light and γ radiation and it is likely, therefore, that they are defective in some common steps in DNA repair. A mutant of E. coli which is sensitive to MMS but only slightly sensitive to u.v. light has been reported by Ljungquist et al. (1976). It proved to be a double mutant with mutations in the polA and the xthA genes, i.e. it is defective in both DNA polymerase I and an endonuclease specific for apurinic DNA. More recently, a new type of MMS-sensitive mutant not sensitive to u.v. light and γ radiation has also been isolated (Yamamoto et al., 1978). The function of the mutated gene is not known and it maps in a different position from the xthA gene. In the case of E. coli K12 it has also been shown that the MMS-sensitivity of rec+ strains is to some extent dependent on the medium in which they are grown (Scudiero et al., 1973). Cells grown in glucose-enriched nutrient broth medium were more resistant than cells grown in nutrient broth only.

The present work shows that treatment of E. coli K12 with MMS results in marked changes in the nucleoid structure. In particular, loss of supercoiling (caused by the introduction of breaks into the DNA) was observed, the supercoiling being partially restored during incubation after the removal of MMS.

**METHODS**

Chemicals and nucleic acids. Polyoxyethylene(20) cetyl ether (Brij-58), ethidium bromide and egg white lysozyme (grade I, 46 360 units (mg protein)

\(^{-1}\) were obtained from Sigma. Sodium deoxycholate and MMS were purchased from Merck, and Sarkosyl NL-97 from Ciba Geigy. Radiochemicals were obtained from The Radiochemical Centre, Amersham. All other chemicals used were reagent grade. \(^{3}H\)-Labelled \(\phi X174\) RF1 (specific activity 0-1 \(\mu\)Ci \(\mu\)g

\(^{-1}\), 3-7 kBq \(\mu\)g

\(^{-1}\)) was a gift from I. F. Nes, Department of Biochemistry, University of Bergen, Norway (Nes & Nissen-Meyer, 1978). \(^{14}C\)-Labelled phage T4 was prepared by the method of Eisenstark (1967).

Bacterial strains. The following strains were used: Escherichia coli K12 DG75 (F- thy leu), E. coli K12 AB2463 (recA thr leu his arg pro), and E. coli p3478 (F+ thyA36 polA1).

Growth conditions. All strains were grown for 2 h at 37 °C in L-broth supplemented with 10 \(\mu\)g thymine ml

\(^{-1}\) and 2 mg glucose ml

\(^{-1}\). Dilutions were then made into the minimal medium of Clark & Maaløe (1967), with the following additions (per ml): for E. coli K12 DG75 (thy leu), 1 \(\mu\)g thiamin, 5 \(\mu\)g thymidine and 80 \(\mu\)g L-leucine; for E. coli p3478 (thyA36 polA1), 1 \(\mu\)g thiamin and 5 \(\mu\)g thymine; for E. coli K12 AB2463 (recA thr leu his arg pro), 1 \(\mu\)g thiamin and 10 \(\mu\)g each of L-threonine, L-leucine, L-histidine, L-arginine and L-proline. After overnight growth at 37 °C, to an \(A_{450}\) of 0-4, the cells were used in the experiments.

Viability after MMS treatment. Both control and MMS-treated cells were harvested by centrifugation at 7500 rev. min

\(^{-1}\) for 5 min in an HB-4 rotor using a Sorvall RC-5 centrifuge. Dilution series were made with minimal medium. Samples of 100 \(\mu\)l were plated on 1-5% (w/v) agar containing the same medium and incubated for 24 h at 37 °C before counting.

Labelling. DNA was labelled with 1-0-30 \(\mu\)Ci [\(\text{methyl-}^{3}\text{H}\)] thymidine ml

\(^{-1}\) (47 Ci mmol

\(^{-1}\), 1-74 TBq mmol

\(^{-1}\)) for 5 min. The DNA in the MMS treated cells was labelled before the addition of MMS. For simultaneous labelling of DNA and RNA, cells were treated with 7-5 \(\mu\)Ci [\(\text{methyl-}^{3}\text{H}\)] thymidine ml

\(^{-1}\) (1 Ci mmol

\(^{-1}\), 37 GBq mmol

\(^{-1}\)) for two generations. In experiments to measure the rate of DNA synthesis, 1 ml samples were withdrawn at the times indicated and were pulse-labelled for 2 min with 0-3-1-25 \(\mu\)Ci [\(\text{methyl-}^{3}\text{H}\)] thymidine ml

\(^{-1}\) (47 Ci mmol

\(^{-1}\)). The number of methyl groups introduced into DNA by MMS was estimated using [\(\text{methyl-}^{14}\text{C}\)] MMS (0-2 mCi mmol

\(^{-1}\), 7-4 MBq mmol

\(^{-1}\)).

*In vitro* MMS treatment. MMS was added to an exponentially growing culture in the minimal medium of Clark & Maaløe (1967). The cells were incubated at 37 °C, pH 7-0, and harvested by filtration on Millipore filters (RAWP 04700, 0-45 \(\mu\)m). In experiments to measure viability, the cells were harvested by centrifugation.

*In vitro* MMS treatment of envelope-free nucleoids. Envelope-free nucleoids were isolated by sucrose-gradient centrifugation (see below). The fractions containing the 1500–1700s nucleoids were treated with various concentrations of MMS at pH 7-0 and at 0, 10, 20 and 37 °C for 30 or 60 min. In addition to MMS, the incubation mixture contained 1 m-NaCl, 5 mm-EDTA and 10 mm-Tris pH 7-0.
Effect of MMS on the bacterial nucleoid

Preparation of envelope-free nucleoids. Approximately 3 ml of an exponentially growing culture with an A_{540} of 0.4 was mixed with 3 ml of solution I (15 mM-NaOH, 25 mM-NaCl). The cells were harvested by centrifugation at 7500 rev. min^{-1} for 5 min in an HB-4 rotor using a Sorvall RC-5 centrifuge. The pellet was resuspended in 400 µl of ice-cold solution II (10 mM-NaOH, 0.1 M-NaCl, 20% sucrose, 10 mM-Tris pH 8.2). A 200 µl portion of this suspension was gently mixed with 50 µl of ice-cold solution III (4 mg egg white lysozyme ml^{-1}, 50 mM-EDTA, 0.12 M-Tris pH 8.2) and incubated for 10 min at 0 °C. A 250 µl portion of ice-cold solution IV (2 mM-NaCl, 10 mM-EDTA, 1% Brij 58, 1% Sarkosyl NL-97, 0.4% sodium deoxycholate) was then added and the mixture was incubated for 10 min at 20 °C. The lysate (400 µl) was slowly (0.8 ml min^{-1}) applied to a gradient of 10–30% (w/v) sucrose containing 1 M-NaCl, 5 mM-EDTA, 1 mM-2-mercaptoethanol and 10 mM-Tris pH 8.2. The gradient tubes were centrifuged at 10000 rev. min^{-1} for 2 h at 4 °C either in an HB-4 rotor using a Sorvall RC-5 centrifuge or in an SW41 Ti rotor using a Beckman L2-65B centrifuge. The lysates were not pre-centrifuged to remove cell debris (Korch et al., 1976). 3H-labelled phage T4 was used as a marker. Approximately 30 fractions per gradient were collected by pumping out from the bottom of the gradient. The fractions were either subjected to cold trichloroacetic acid treatment, filtered on Gelman glass fibre filters (type A-E) and washed three times with cold trichloroacetic acid, or alternatively 100 µl samples of each fraction were applied to Whatman 3MM filters. All filters were dried in a vacuum oven at 80 °C for 45 min and counted in 2.5 ml of a toluene-based scintillation fluid.

Determination of sedimentation coefficients. Calibration of the 10–30% sucrose gradient system using phage T4 gave a linear correlation between R_{p} value and sedimentation coefficient in the range 500S to 2000S (Korch et al., 1976). The sedimentation coefficients were not corrected for rotor speed effects (Hechtl et al., 1977).

Measurement of RNA co-sedimenting with the envelope-free nucleoids. Lysates were made from cells labelled with 15-3H]-uracil for two generations. Centrifugation and fractionation of the gradients were carried out as described above and the fractions were analysed for DNA and RNA according to Kennel (1967).

Titration of supercoiling. Bacterial lysates were prepared as described above. Samples of 100 µl from the same lysate were applied to gradient tubes containing different concentrations of ethidium bromide. The gradient tubes were then centrifuged at 10000 rev. min^{-1} for 2 h at 4 °C in an SW41 Ti rotor using a Beckman L2-65B centrifuge and fractionated as described above, and the sedimentation coefficient of the nucleoids was determined.

Determination of molecular weight of DNA by centrifugation in alkaline sucrose gradients. Lysates from MMS-treated and untreated cells were prepared as described above. Samples of 200 µl of the lysate were layered on to 5 ml gradients of 5–20% sucrose containing 0.3 M-NaOH, 1 M-NaCl and 5 mM-EDTA. The gradients were centrifuged at 40000 rev. min^{-1} for 80 min at 4 °C in an SW50-1 Ti rotor using a Spinco L-50 centrifuge. 

\[ \phi X174 \]

RFI was used as an internal marker in all gradients. The molecular weights were calculated using the equation of Studier (1965) for alkaline single-stranded DNA. The number of single-strand breaks was estimated from the equation \( N = \left( \frac{M_p}{M_n} \right) - 1 \), where \( N \) is the number of single-strand breaks, \( M_p \) is the molecular weight of nicked DNA and \( M_n \) is the molecular weight of non-nicked DNA.

Determination of the number of methyl groups introduced into DNA by MMS. The cells were grown in the presence of 25 mM-[14C]-MMS (210 µCi mmol^{-1}) for 1 h at 37 °C. DNA, RNA and protein were separated according to Kennel (1967), and the radioactivity in each fraction was determined.

Determination of the number of single-strand breaks plus apurinic sites in DNA after MMS treatment. \( \phi X174 \) RFI (0.64 µg ml^{-1}) labelled with [methyl-3H]thymidine (0–1 µCi µg^{-1}) was incubated with 25 mM-MMS for 60 min at 37 °C in a buffer containing 10 mM-EDTA and 10 mM-Tris pH 7.6. Samples of 200 µl were applied to alkaline 5–20% sucrose gradients and centrifuged at 40000 rev. min^{-1} for 4 h at 4 °C in an SW41 Ti rotor using a Beckman L2-65B centrifuge. The number of single-strand breaks plus apurinic sites was calculated according to Brent (1975).

Determination of breaks due to non-enzymic hydrolysis of apurinic sites and triester breakage in MMS-treated \( \phi X174 \) RFI. \( \phi X174 \) RFI was treated with MMS as described in the preceding section. Samples of 200 µl were applied to gradients of 5–20% sucrose containing 10 mM-EDTA and 10 mM-Tris pH 7.6 and centrifuged at 40000 rev. min^{-1} for 7.5 h in an SW41 Ti rotor using a Beckman L2-65B centrifuge. The number of breaks was determined by the conversion of the RFI to the RFII form.

Transmission electron microscopy of E. coli. The bacteria were immediately chilled and fixed with glutaraldehyde and osmium tetroxide, then embedded and post-stained according to Kruger & Bloom (1974). Thin sections were examined in a Philips EM300 electron microscope.

RESULTS

Effect of MMS on growth and morphology of E. coli K12 DG75

Escherichia coli K12 DG75 was used for most of the experiments reported here since this strain has been employed extensively in other studies on nucleoids (Worcel & Burgi, 1975; Korch et al., 1976; Øvrebø & Korch, 1978). Prior to the nucleoid experiments it was necessary to investigate the influence of MMS on growth, survival and morphology of this
strain. The rate of growth, as measured by the increase in the $A_{450}$, decreased approximately 50% in the presence of 10 mM-MMS, whereas 25 mM-MMS caused at least 90% inhibition. Plating for surviving bacteria showed that treatment with 25 mM-MMS for 1 h at 37 °C yielded approximately 2% surviving cells. The corresponding number with 10 mM-MMS was approximately 20%. The survival decreased linearly with time when plotted semilogarithmically. From these results it was concluded that $E. coli$ K12 DG75 resembles other strains not sensitive to MMS (Lungquist et al., 1976). The influence of MMS on DNA and RNA synthesis in $E. coli$ K12 DG75 is shown in Fig. 1. MMS at 25 mM caused almost complete inhibition of both DNA and RNA synthesis.

The number of methylated bases in the DNA of $E. coli$ K12 DG75 was measured using $[14C]MMS$. After incubation for 1 h with 25 mM-MMS, 50% of the radioactivity was found in the protein fraction, 41% in RNA and 9% in DNA. In the case of DNA it was established that approximately 0.6% of the bases had been methylated.

Thin sections of $E. coli$ K12 DG75 treated with MMS were examined by transmission electron microscopy. Some representative examples are shown in Fig. 2. The nuclear areas are less visible in the MMS-treated cells compared with the control cells. Another characteristic feature of the MMS-treated cells is their loss of shape and septum formation and an increase in the periplasmic space, particularly evident at the ends of the cells. Examination of MMS-treated cells by phase-contrast microscopy showed that the nuclear zone in these cells became less visible with time (results not shown).

**Effect of MMS on the sedimentation properties of envelope-free nucleoids**

The banding pattern of envelope-free nucleoids isolated from untreated cells of $E. coli$ K12 DG75 showed a symmetrical peak with a sedimentation coefficient of approximately 1600S (Fig. 3a). No change in the sedimentation coefficient was observed when the cells were treated with 25 mM-MMS for 30 min (Fig. 3b), but after 60 min the sedimentation coefficient had decreased to approximately 850S (Fig. 3c). With 10 mM-MMS there was no change in the sedimentation coefficient after 30 min treatment, but after 60 min it had decreased to approximately 1350S (results not shown).
The influence of MMS treatment on the sedimentation properties of isolated envelope-free nucleoids was also investigated. Treatment of isolated nucleoids with 25 mM-MMS for 30 or 60 min caused no change in the sedimentation coefficient (results not shown).
Fig. 3. Sedimentation pattern in 10–30% sucrose gradients of envelope-free nucleoids from MMS-treated *E. coli* K12 DG75. The DNA in all fractions was precipitated with cold trichloroacetic acid. Phage T4 was used as a marker. Further details are given in Methods. (a) Control; (b) cells treated with 25 mM-MMS for 30 min at 37 °C before lysis; (c) cells treated with 25 mM-MMS for 60 min at 37 °C before lysis.

Fig. 4. Sedimentation pattern in 10–30% sucrose gradients of envelope-free nucleoids from MMS-treated *E. coli* p3478 (polA). Phage T4 was used as a marker. (a) Control; (b) cells treated with 25 mM-MMS for 60 min at 37 °C before lysis.

Experiments were also carried out with two MMS-sensitive strains, *E. coli* p3478 (polA) and *E. coli* K12 AB2463 (recA). In both cases the nucleoids isolated from untreated cells had a sedimentation coefficient of approximately 1600S. When these strains were treated with MMS, the cell lysates became very viscous and no sharp nucleoid peak was observed. Results for the polA strain are shown in Fig. 4. Similar results were obtained with the recA strain.

**Loss of supercoiling during MMS treatment**

The marked change in the sedimentation coefficient of nucleoids that occurred when *E. coli* K12 DG75 was treated with MMS could be due to several factors, such as loss of RNA and therefore changes in the DNA:RNA ratio of the nucleoid, or nicking of DNA resulting in decreased supercoiling with a partial unfolding of the nucleoid. By labelling the nucleoid with [3H]uracil the amounts of DNA and RNA in the nucleoid could be estimated (Table 1). The
Effect of MMS on the bacterial nucleoid

Table 1. RNA content of envelope-free nucleoids from cells treated with MMS

The cells were labelled with [5-3H]uracil for two generations and treated with MMS for 60 min at 37 °C before lysis. The envelope-free nucleoids were isolated by sucrose-gradient centrifugation and RNA and DNA were determined according to Kennel (1967).

Fig. 5. Sedimentation coefficient as a function of ethidium bromide concentration for envelope-free nucleoids from MMS-treated E. coli K12 DG75. Further details are given in Methods. Control (○); cells treated with 25 mM-MMS for 1 h at 37 °C before lysis (●).

results show that the DNA : RNA ratio in the nucleoid was the same in the MMS-treated and in the control cells.

The amount of supercoiling in the nucleoid can be determined by titration with ethidium bromide (Worcel & Burgi, 1972). Increasing concentrations of ethidium bromide were used in a set of sucrose gradient tubes, and for each concentration the sedimentation coefficient of the nucleoid was calculated. The result from one such experiment is shown in Fig. 5. In the control a minimum sedimentation coefficient was observed at a concentration of ethidium bromide of approximately 2 µg ml⁻¹. Above this concentration the sedimentation coefficient again increased and reached the initial value at a concentration of ethidium bromide of 4 µg ml⁻¹. The pattern obtained for the control is similar to that reported by other groups (Worcel & Burgi, 1972; Pettijohn & Hecht, 1973). In the case of the nucleoids isolated from cells that had been treated with 25 mM-MMS for 1 h, increasing concentrations of ethidium bromide had little effect on the sedimentation coefficient. These results suggest that the nucleoid from the MMS-treated cells had lost almost all its supercoiling. This could have been caused by repair nucleases which introduce single-strand breaks in the DNA at modified sites or by
Fig. 6. Sedimentation pattern in alkaline 5–20% sucrose gradients of DNA from MMS-treated *E. coli* K12 DG75. φX174 RFI was used as a marker. (a) Control; (b) cells treated with 10 mM-MMS for 1 h at 37 °C before lysis; (c) cells treated with 25 mM-MMS for 1 h at 37 °C before lysis.

chemical depurination followed by enzymic or chemical hydrolysis of apurinic sites, or by a combination of these factors.

An estimate of the number of breaks plus apurinic sites in the nucleoid from MMS-treated cells was obtained by carrying out alkaline sucrose-gradient centrifugations of nucleoid preparations (Fig. 6). A near-symmetrical distribution in the size of DNA fragments was obtained for nucleoids from cells treated with 10 mM-MMS or with 25 mM-MMS. Based on molecular weight estimation it was calculated that the nucleoids from cells treated with 10 and 25 mM-MMS had, on average, 42 and 100 breaks plus apurinic sites per genome, respectively. In the case of the nucleoid from the *polA* strain treated with 25 mM-MMS (Fig. 4), similar centrifugation experiments gave a value of approximately 300 breaks plus apurinic sites per genome.

To obtain an estimate of apurinic sites in the DNA caused by non-enzymic depurination, 3H-labelled φX174 RFI was methylated in vitro, using the same methylating conditions as those used for *E. coli* cells in vivo. Figure 7 shows the results obtained when φX174 RFI treated with 25 mM-MMS was subjected to alkaline and neutral sucrose-gradient centri-
Effect of MMS on the bacterial nucleoid

Fig. 8. Incorporation of [3H]thymidine during and after treatment of *E. coli* K12 DG75 with 25 mM-MMS at 37°C. MMS was added to a culture of exponentially growing cells at *t* = 0. At *t* = 60 min, cells were filtered (Millipore RAWP, 0.45 μm) and resuspended in MMS-free minimal medium. Samples of 1 ml were withdrawn at the times indicated and pulse-labelled with [methyl-3H]thymidine.

Fig. 9. Sedimentation pattern of envelope-free nucleoids from *E. coli* K12 DG75 incubated in MMS-free medium for various periods after MMS treatment. The cells were treated with 25 mM-MMS for 1 h at 37°C, harvested by centrifugation, resuspended in MMS-free medium and incubated for the times indicated prior to lysis. Nucleoids from untreated cells in the exponential growth phase were used as controls. Further details are given in Methods. (a, b) Neutral 10–30% sucrose gradients: control (○); 0 h incubation (□); 1 h incubation (■); 2 h incubation (●). Fig. 10. Sedimentation coefficient as a function of ethidium bromide concentration for envelope-free nucleoids from *E. coli* K12 DG75 incubated in MMS-free medium after MMS treatment. The cells were treated with 25 mM-MMS for 1 h at 37 °C, harvested by centrifugation, resuspended in MMS-free medium and incubated for 1 h (∆) or 2 h (▲) prior to lysis. Further details are given in Methods.

Removal of MMS caused a large increase in the incorporation of thymidine (Fig. 8), suggesting that extensive repair synthesis took place. After 1 h the rate of incorporation had levelled off and was approximately half that prior to the MMS treatment. The sedimentation properties of the nucleoid after various periods allowed for repair were investigated; the results for 1 h and 2 h incubation periods are shown in Fig. 9. After 1 h incubation in MMS-free medium an increase in sedimentation coefficient of the nucleoid from approximately 850S to 1350S was observed; after 2 h the sedimentation coefficient was the same as that of the control. This might suggest that increased folding of the nucleoid occurs during the repair period, i.e. the supercoiling was partially restored. Alkaline sucrose-gradient centrifugation showed that the number of breaks plus apurinic sites was reduced from 100 to the same level as in the control during a repair period of 2 h.

The isolated nucleoids from the cells in which repair had taken place were titrated with ethidium bromide to estimate supercoiling (Fig. 10). For both the 1 h and 2 h samples, addition of increasing amounts of ethidium bromide produced a marked decrease in the sedimentation coefficient of the nucleoids. In the case of the 1 h sample a plateau was observed at 800S. With the 2 h sample a minimum was seen at a concentration of ethidium bromide of approximately 1.5 µg ml⁻¹, followed by a maximum at 2.5 µg ml⁻¹ and a plateau region of approximately 1300S. Since the sedimentation coefficient of the nucleoid and the number of breaks plus apurinic sites were the same for the 2 h sample as for the control, one
would expect the ethidium bromide titration curve of this sample to be similar to that of the control. The reasons for the differences are not fully understood at present.

**DISCUSSION**

The present results clearly demonstrate that the methylating agent MMS causes profound changes in the nucleoid structure of *E. coli* K12 DG75 at concentrations which rapidly inhibit the growth of the cells.

It is known that MMS reacts fairly rapidly with biological macromolecules (Singer, 1975). With 25 mM-MMS, changes in the nucleoid structure were first seen after 1 h. The same concentration of MMS caused almost immediate inhibition of growth. The decrease in sedimentation coefficient observed is probably caused by relaxation of supercoils in the nucleoid. Relaxation of supercoils has also been demonstrated in vitro after treatment with DNAase (Worcel & Burgi, 1972; Pettijohn & Hecht, 1973). In the present case 25 mM-MMS gave an average of 100 breaks plus apurinic sites per genome after 1 h incubation in vivo. Models for the isolated nucleoid suggest that it consists of a number of independent loops which can be relaxed separately (see Kleppe et al., 1979). Estimates of the number of loops have varied; the most recent study suggests a number of 100 ± 30 (Lydersen & Pettijohn, 1977). The average number of breaks plus apurinic sites created by 25 mM-MMS in 1 h is therefore about the same as the number of loops in the nucleoid. Furthermore, it is also approximately the same as that found in DNAase-treated nucleoids of similar sedimentation coefficient (Worcel & Burgi, 1972). Therefore, it is likely that the breaks plus apurinic sites determined in this work in fact consist mostly of breaks. Relaxation of supercoils in the nucleoid leads to a loss of the tertiary structure and this would be in agreement with the light and electron microscope observations of MMS-treated cells.

The fact that no change in the sedimentation coefficient of the nucleoid was observed after short periods of MMS treatment, despite the fact that increasing numbers of breaks could be demonstrated, might suggest that the supercoils are partially restrained in vivo. An effect on the sedimentation coefficient would therefore first be observed only after a considerable number of breaks had been introduced. A similar conclusion has been reached by Pettijohn & Pfenninger (1979) using γ rays to produce nicks in DNA in vivo.

A change in the amount of RNA in the nucleoid might, however, also explain the decrease in the sedimentation rate, since RNA is known to stabilize the isolated nucleoid (Pettijohn & Hecht, 1973; Hecht & Pettijohn, 1976). DNA and RNA analyses showed, however, that the DNA : RNA ratio remained unchanged during the MMS treatment.

The question must now be considered as to the mechanism of induction of breaks in the DNA strands of the nucleoid. An extensive review of repair mechanisms, dealing also with MMS, has recently been published (Roberts, 1978). In addition to methylation of bases, MMS can cause both depurination and strand breakage (Laurence, 1963; Lawley, 1966; Lindahl & Andersen 1972; Singer, 1975). It appears that in bacteria the methylated bases are not excised to any extent when MMS is used as a methylating agent (Prakash & Strauss, 1970). With other methylating agents such as N-methyl-N'-nitro-N-nitrosoguanidine, excision of certain methylated products can be demonstrated (Lawley & Orr, 1970). Studies with φX174 RFI DNA in this work showed that apurinic sites were produced by incubation of the DNA with MMS. Apurinic sites could also have been created by the enzyme 3-methyl adenine glycosylase (Lindahl, 1976) and other glycosylases. The apurinic sites thus created could then serve as substrates for the apurinic specific endonucleases (AP endonucleases) of *E. coli* (Verly & Paquette, 1972; Radman, 1976; Ljungquist, 1977; Gates & Linn, 1977; Gossard & Verly, 1978), resulting in strand breakage. The fact that MMS treatment in vitro of the isolated nucleoid caused no significant change in the sedimentation coefficient suggests that non-enzymic hydrolysis of apurinic sites is of little importance. Control experiments with φX174 also confirmed this view.
In the two MMS-sensitive strains studied, the chromosome contained considerably more strand breaks after MMS treatment than that in the insensitive strain. This would then result in increased viscosity of the DNA and complete collapse of the tertiary structure of the nucleoid. DNA from such MMS-treated cells is known to be of relatively small molecular weight when examined in alkaline sucrose gradients (Boris et al., 1971). This was also confirmed in the present work. Cell lethality might therefore, as previously suggested (Scudiero et al., 1973), be a consequence of increased amounts of non-repaired breaks in the DNA. The destruction of the nucleoid structure which occurs as a result of the increased number of gaps in the DNA may also have far-reaching implications with regard to the control of important processes such as transcription, separation of chromosomes and DNA replication. Thus, for repair to be complete it must be assumed that the supercoiling, which is lost, must be introduced again into the chromosome so that the original nucleoid structure is restored.

Treatment of bacteria with MMS obviously affects other control mechanisms in the cell in addition to those connected with the chromosome. The methylation of, for example, membrane proteins and ribosomes is probably also of great importance with regard to growth inhibition (Singer, 1975). The electron microscope results in this work revealed that MMS also caused alterations in the cell envelope. Further studies are needed to establish in more detail the influence of MMS on the various metabolic processes.

The mechanism of action of other methylating agents on the nucleoid structure might be different from that of MMS. Results from our laboratory (unpublished) have shown that mitomycin C at low concentrations causes rapid and profound changes in the tertiary structure of the nucleoid from E. coli.

This study was supported in part by a grant from the Norwegian Research Council for Science and Humanities. We are grateful to Drs C. Korch and S. Øvrebø for many helpful discussions.
