(Received 26 October 1982; revised 14 December 1982)

Cultures of the cyanobacterium Anacystis nidulans were grown under conditions of Mg²⁺-limitation and Mg²⁺-excess. Cell-free extracts, obtained after sonication and centrifugation (45 000 g, 60 min), were analysed on polyacrylamide gels. Mg²⁺-limited cells, in which cell division was inhibited, accumulated a protein of molecular weight 50 × 10³. Only small amounts of this protein were detected in non-Mg²⁺-limited cultures. A protein of molecular weight 36 × 10³, found in non-Mg²⁺-limited cells, was not detected in Mg²⁺-limited cells. When a Mg²⁺ shift-up from 5 μM to 1 mM was carried out in a chemostat, synthesis of the 36 × 10³ protein was initiated and the amount of the 50 × 10³ protein decreased whilst the main protein pattern remained unaltered. The possibility that the two proteins are involved in cell division is discussed.

INTRODUCTION

In Mg²⁺-limited chemostats the cyanobacterium Anacystis nidulans grows as filaments without septa or transverse walls. In batch cultures an increase in the Mg²⁺ concentration from 5 μM to 1 mM results in a synchronized division of the filaments into smaller cells about 90 min after the elevation of the Mg²⁺ concentration (Utkilen, 1982). This synchronized cell division occurs without a change in overall rates of DNA or protein synthesis, but protein synthesis has been shown to be necessary to obtain the cell division (Utkilen, 1982). It has also been shown (Mann & Carr, 1977) that protein synthesis occurring at the termination of DNA replication is required for cell division to take place in A. nidulans.

Evidence from other prokaryotes suggests that septal formation and cell division require synthesis of specific proteins (Inouye & Pardee, 1970; Smith & Pardee, 1970; Ahmed & Rowbury, 1971; Grula & King, 1971; Ingram & Fisher, 1973). In this paper we present evidence that Mg²⁺-limitation prevents accumulation of a specific protein and enhances the accumulation of another. Both these proteins may be concerned with cell division.

METHODS

Organism. Anacystis nidulans strain UTEX 625 of the Culture Collection of Algae, Department of Botany, University of Texas, was used.

Growth conditions. The continuous cultures have been described earlier (Utkilen, 1982); they were fed with the modified medium C (Utkilen, 1982) containing 5 μM-Mg²⁺. The growth temperature was 40 °C and the dilution rate (D) 0.09 h⁻¹. The culture vessel was placed between two ranks of fluorescent tubes (Utkilen, 1982), which gave an incident light intensity of 445 μE m⁻² s⁻¹ (32.5 klx) at both sides of the culture vessel. This was the light intensity used during Mg²⁺-limited growth, where the mean cell volume was about 2 μm³. At light intensities of 108 μE m⁻² s⁻¹ (7.6 klx) or lower, the mean cell volume in the same culture was about 0.9 μm³. This is the cell size obtained when Mg²⁺ is not limiting cell division (Utkilen, 1982). Therefore 108 μE m⁻² s⁻¹ was used to obtain ‘normal’ cell division under the same growth conditions and this is referred to as a ‘non-Mg²⁺-limited culture’ in
this work. The light intensity was measured by LI 1854 Quantum/Radiometer/Photometer (Lambda Instruments Corporation, U.S.A.) and it was altered by placing white paper sheets between the fluorescent tubes and the waterbath.

Magnesium shift-up experiments in the continuous culture were carried out by increasing the Mg$^{2+}$ concentration in the growth vessel to 1 mM, by adding MgCl$_2$, and changing the reservoir to one with medium containing 1 mM-Mg$^{2+}$.

Non-Mg$^{2+}$-limited batch cultures were grown in Roux flasks containing 800 ml of the above medium with the Mg$^{2+}$ concentration increased to 1 mM by adding MgCl$_2$. The Roux flasks were placed in the same waterbath as that used for the continuous cultures, and were aerated with the same air/CO$_2$ (95:5, v/v) mixture as the other cultures. The specific growth rate under these conditions was about 0.2 h$^{-1}$, and the cells were always harvested during exponential growth.

**Protein extraction and sample preparation.** Cells were harvested by centrifugation (10000 g, 10 min), washed once with distilled water and stored frozen at $-20^\circ$C. The frozen cells (15-20 mg dry weight), resuspended in 0.5-1.0 ml 65 mM-Tris/HCl buffer, pH 6.8, were disrupted by sonication (Soniprep 150, MSE, U.K.) for 4 × 1 min at 0°C and centrifuged (45000 g, 60 min). Sucrose, SDS, dithiothreitol and Bromophenol Blue were added to the supernatant to give final concentrations (w/v) of 15%, 2%, 2% and 0.001%, respectively. The mixture was heated at 100°C for 5 min before loading on the SDS-PAGE gels.

For isoelectric focusing, protein samples were prepared essentially according to O'Farrell (1975) with the modifications of Petersen et al. (1979).

Protein concentrations were determined by the Lowry method using bovine serum albumin (Sigma) as standard.

**One- and two-dimensional gel electrophoresis.** SDS-PAGE on a 8-18% (w/v) linear gradient slab gel was run according to Laemmli (1970) with one modification: the ratio of acrylamide: N,N'-methylenebisacrylamide was 44:0.8 in the separating gel. The gels were fixed overnight in 50% (v/v) methanol, 10% (v/v) acetic acid, stained for 3 h with Coomassie Brilliant Blue (0.1% in fixative) and destained by diffusion in the same fixative. Bio-Rad's low molecular weight markers were used as standards for molecular weight determinations. The gels were scanned at 570 nm in a Gilford 240 spectrophotometer with the corresponding linear transport attached.

Isoelectric focusing and two-dimensional gel electrophoresis was carried out according to O'Farrell (1975) with the 8-18% (w/v) linear gradient as the second dimension gel. The proteins on these gels were visualized with the silver staining method as described by Oakley et al. (1980).

**RESULTS AND DISCUSSION**

The electrophoretic band pattern of proteins from extracts of *A. nidulans* grown in Mg$^{2+}$-limited and non-Mg$^{2+}$-limited continuous cultures, and in non-limited batch cultures, showed several quantitative differences (Fig. 1). Most of these differences were presumably due to the variation in growth conditions, as can be seen for the phycoerythrin (PC in Fig. 1). Extracts from the low light (108 µE m$^{-2}$ s$^{-1}$) culture contained more of this light-harvesting protein than those from the two other cultures and they were easily identified by their blue colour even during electrophoresis.

When looking for obvious differences between the extracts from the filamentous cells (Mg$^{2+}$-limited), where the mean cell volume was about 2 µm$^3$, and both extracts from the 'normal-sized' cells, where the mean cell volume was 0.9 µm$^3$, two protein bands, X and Y (Fig. 1), were suspected to be connected with cell division. Band X-protein was found in the extracts from non-Mg$^{2+}$-limited continuous and batch cultures, but it was missing from the extract from Mg$^{2+}$-limited cells. Band Y-protein, which accumulated in the filamentous Mg$^{2+}$-limited cells, was missing or was present at a low concentration in the extracts from the other cultures. X- and Y-proteins had molecular weights of $36 \times 10^3$ and $50 \times 10^3$, respectively (Fig. 1).

Gel patterns of the non-soluble proteins remaining in the pellets after the 45000 g, 60 min centrifugation showed no differences in protein composition between the Mg$^{2+}$-limited and non-Mg$^{2+}$-limited cells (results not shown).

By using two-dimensional gel electrophoresis and visualizing the proteins with silver staining, 300-400 proteins were detected, but only a few differences in protein patterns were found between the non-Mg$^{2+}$-limited and Mg$^{2+}$-limited continuous cultures (Fig. 2). The most obvious difference was a protein located at the same position as the band X-protein in Fig. 1, which in Fig. 2 also is missing from the Mg$^{2+}$-limited cultures. This protein was therefore identified as band X-protein; it had a pI value of 5.3. It is also possible to locate the Y-protein in Fig. 2, since a
protein found in the same position as the band Y-protein in Fig. 1 was present in much larger quantities in the extracts from Mg$^{2+}$-limited cells (Fig. 2b) than in that from the non-Mg$^{2+}$-limited cells (Fig. 2a). This protein had a pI value of 5.4.

It is possible that proteins X and Y are connected with cell division in *A. nidulans*, but the only evidence from the experiments so far was their presence or absence in the filamentous cells. One way to obtain better evidence for a possible link between cell division and the two proteins was to initiate cell division in the filamentous cells and look for alterations in the protein bands. A Mg$^{2+}$ shift-up from 5 μM to 1 mM has been shown to induce a synchronized cell division in filamentous *A. nidulans*, while the rate of protein synthesis was not affected by this treatment (Utkilen, 1982). Thus, a Mg$^{2+}$ shift-up initiated cell division without altering the main protein pattern and therefore variations in only the band X- and Y-proteins might be found if these proteins are indeed connected with septum formation and cell division. When a similar Mg$^{2+}$...
Fig. 2. Two-dimensional gel electrophoresis of supernatant proteins from crude extracts of *A. nidulans* grown in (a) non-Mg\(^{2+}\)-limited and (b) Mg\(^{2+}\)-limited continuous cultures at \(D = 0.09\) h\(^{-1}\). The first dimension was isoelectric focusing (IEF) in a pH gradient from 5 to 7 and the second dimension was SDS–PAGE. The X-protein is ringed in (a) and the Y-protein is ringed in (b). The arrows mark the orientation spots. Each sample contained 30 µg protein.
Fig. 3. Protein patterns of crude extracts of *A. nidulans* after a Mg$^{2+}$ shift-up from 5 μM to 1 mM in a continuous culture at $D = 0.09$ h$^{-1}$. An extract from a low light continuous culture (b) was used to locate the position of the X-protein, and an extract from another Mg$^{2+}$-limited culture (a) was used for comparison with the zero time sample. Each sample contained 50 μg protein.
shift-up was done in a chemostat (see Methods), it was found (Fig. 3) that the main protein pattern was unaltered while band X-protein started to accumulate and band Y-protein decreased. Since no alterations were found in the other protein bands, Fig. 3 also indicates that the other quantitative differences found between the extracts from Mg\(^{2+}\)-limited cells and the non-limited cells (Fig. 1) are not important in connection with cell division.

The rate of increase in X- and decrease in Y-protein after the Mg\(^{2+}\) shift-up were demonstrated by scanning the gels (Fig. 4).

Lutkenhaus & Donachie (1979) have identified a cell division protein of the *ftsA* gene in *Escherichia coli* with a molecular weight of 50 × 10³. The synthesis of this protein is required throughout septation and it cannot be re-utilized and is therefore probably used in the process of septation. Cell division in *A. nidulans* might be controlled in the same way as for *E. coli*, since they both have a Gram-negative type of wall. For this reason the Y-protein with a molecular weight of 50 × 10³ in *A. nidulans* could have the same functions as the 50 × 10³ molecular weight protein in *E. coli*.

There is evidence that initiation of cell division in non-photosynthetic prokaryotes involves accumulation of a 'division protein' (Smith & Pardee, 1970; Ahmed & Rowbury, 1971). Results obtained for the cyanobacterium *Agmenellum quadruplicatum* (Ingram & Fisher, 1973) indicate that an effector molecule has to accumulate at regions of potential cell division in order to initiate the invagination of cell membrane and cell wall. Even in some eukaryotic organisms, such as *Tetrahymena pyriformis* (Wheatley et al., 1979) and *Physarum polycephalum* (Sachsenmaier et al., 1972), cell division has been shown to depend on the accumulation of an initiator protein. The possibility that a 'division protein' has to accumulate in *A. nidulans* in order to initiate cell division therefore seems to be in accordance with results obtained for other organisms. It has also been shown that the induction of a synchronized cell division in Mg\(^{2+}\)-limited *A. nidulans* by a Mg\(^{2+}\) shift-up required protein synthesis (Utkilen, 1982), and Mann & Carr (1977) have shown that protein synthesis occurring at the termination of DNA replication is necessary for cell division to take place in this organism.

Our preliminary hypothesis, based on the results in the present paper, is as follows. When *A. nidulans* is grown at 5 μM-Mg\(^{2+}\), there is inhibition of synthesis of a protein (X) which has to accumulate to a certain concentration before septum formation and cell division can occur. Since these growth conditions do not influence growth or cell mass increase (Utkilen, 1982), the resulting delay in cell division produces filamentous forms of this cyanobacterium. The synthesis of the Y-protein, which might be used during formation of the septum or transverse wall, is not affected by the low Mg\(^{2+}\) conditions used and therefore accumulates when cell division is delayed by low concentrations of this ion.

Mg\(^{2+}\)-limited growth in chemostats seems to be a good tool for studying control mechanisms
in cell division, since alterations in cell division proteins can be induced without altering the main pattern of protein synthesis. The system might also work for other prokaryotes since several of them have been shown to become filamentous during Mg\(^{2+}\)-limited growth (Webb, 1949). Cell division in eukaryotes might also be investigated in such a system, since Schizosaccharomyces pombe (Ahlulwalia et al., 1978) and Chlorella (Retovsky & Klasterka, 1961) became enlarged when deprived of Mg\(^{2+}\).

The authors thank Dr A. Lovlie, Dr J. Ormerod and cand. real. W. Davies for critical reading of the manuscript.
