(Received 22 February 1984; revised 27 April 1984)

Bakers' yeast (Saccharomyces cerevisiae) has been grown in continuous culture using a control medium and media which contained low levels of ammonium and phosphate. The effects of medium composition and growth rate on the levels of intermediates of the glycolytic pathways, the tricarboxylic acid cycle and the glyoxylate cycle were investigated. The energy charge varied only between 0.7 and 0.9 over the range of dilution rates studied; however, the level of ATP decreased by 50% at higher aerobic growth rates. Intermediates of the Embden–Meyerhof–Parnas pathway were higher at the low aerobic growth rates and decreased as the dilution rate was increased. However, higher levels of these intermediates were also observed at even higher dilution rates at which ethanol formation and fermentative metabolism occurred. Significant differences in levels of intermediates were observed between control experiments and fermentations using the low nitrogen and phosphate media. The greatest differences were observed in the levels of glucose 6-phosphate, 6-phosphogluconate, pyruvate, citrate and glyoxylate. Twenty-one different steady states were investigated and each was found to have a unique composition.

INTRODUCTION

The growth of yeast in aerobic and anaerobic conditions is of considerable commercial interest and has been extensively studied (Sols et al., 1971). Recent work has emphasized the effect of growth rate and carbohydrate status on respiratory adaptation in yeast (Barford & Hall, 1979; Wales et al., 1980; Fiechter et al., 1981).

The level of nitrogen and phosphate in the media can markedly influence the physiological properties of bakers' yeast, particularly its activity and stability. However, it has not been possible to correlate this with any biochemically defined cell parameters (Burrows, 1970, 1979). When fermentations which produce a defined product, e.g. citric acid or penicillin, are studied, it is possible to monitor the 'fitness' of the organism by the rate of product formation. It is less easily monitored with a product such as bakers' yeast where many properties contribute to the quality of the product. However, it should be possible to correlate the 'fitness' with a given metabolic state which can be defined by the relative activity of different metabolic pathways. This can be evaluated by investigating either the level of enzymes involved in these pathways or the level of the relevant intermediates.

In these studies, we have attempted to identify the different metabolic states which may be important in determining the properties of aerobically grown yeast by measuring the level of a range of intermediates. The effect of varying growth rate and the level of nitrogen and phosphate in the medium on these metabolic states has been investigated. The levels of intermediates, however, do not give any information on flux rates through individual metabolic pathways in the cell.
METHODS

Organism and culture media. Saccharomyces cerevisiae strain GB 2333 was provided by Distillers Company (Yeast) Ltd, Glenochil Technical Centre, Menstrie, UK. It was maintained on a medium containing malt extract 0·3%, yeast extract 0·3%, glucose 1% and peptone 0·5% and stored at 4 °C. Inoculum was prepared by growing the yeast in the experimental medium in a 500 ml shaken flask and inoculating the fermenter at 1 · 10⁶ cells ml⁻¹.

The experiments were carried out using a defined mineral salts medium (Oura, 1974) in which the concentration of biotin was increased to 3 mg l⁻¹. Glucose, ammonium sulphate and phosphate levels were varied to give the required experimental conditions. Glucose was varied from 3% (w/v) at low dilution rate to 1% at higher dilution rates. The ratio of glucose to ammonium sulphate to phosphate in the control medium was 36·9:1 and this was altered to 38·5:1 in the low nitrogen medium and 125·30:1 in the low phosphate medium.

Fermentation techniques. The yeast was grown in continuous culture using a Biotec FL301 fermenter with a working volume of 3 litres. The temperature was maintained at 30 ± 0·3 °C and the pH was controlled at 4·6 ± 0·05 by the addition of 1·5 M-KOH. Aeration was controlled up to 4 fermenter volumes of air min⁻¹ and oxygen tension was recorded using a Biotec glass O₂ electrode. Dry weight of cells was determined by filtration through a Millipore membrane filter, pore size 2 µm, drying at 105 °C for 24 h and cooling in a desiccator, and weighing to constant weight. Glucose in the medium was assayed by the glucose oxidase method (Bergmeyer & Bernt, 1974) and ethanol by the alcohol dehydrogenase method of Bernt & Gutman (1974).

Sampling techniques and analysis of cellular intermediates. A 30 ml syringe loaded with precooled (−20 °C) 36% (w/v) HClO₄ was used to sample the fermenter. The volume of culture removed was selected to give 0·25 g dry weight in a final concentration of 6% HClO₄. The total time for collection of the sample was <0·5 s. This method ensures rapid mixing of acid with the culture sample as turbulence is maintained throughout the sampling period. The acidified cell suspension was filtered rapidly through a Millipore Polyvic filter (pore size 0·45 µm), and broken in a Braun Homogenizer (Braun, Melsungen, FRG) using glass beads (mesh size 40). Homogenization was carried out at 4000 r.p.m. for 45 s under a spray of liquid carbon dioxide to maintain the temperature between 0 and 4 °C. The homogenate was centrifuged at 3500 r.p.m. for 10 min at 4 °C in a refrigerated centrifuge and the supernatant adjusted carefully with 5 M-K₂CO₃ to pH 5. Samples were stored on ice and assayed immediately for metabolites. Measured amounts of metabolites were added to the acidified cell suspension prior to the homogenization step in order to evaluate the extraction procedure.

Assay of intermediates. All assays were routinely standardized using freshly prepared standard solutions of the metabolites. ATP was measured by the luciferin–luciferase method of Lundin & Thore (1975). The intensity of light produced on injection and rapid mixing of firefly-lantern-extract (FLE-250, Sigma) to the sample was measured with a Quantum photometer 9511 (Ortec, Bracknell, UK) using a logarithmic scale, and the peak height was recorded on a chart recorder. A calibration curve was produced using ATP standard solutions within the range 10⁻⁵ to 10⁻¹⁰ m-ATP. Other metabolites in the neutralized extracts were determined enzymically by coupling reactions resulting in the oxidation or reduction of NAD as described by Estabrook & Maitra (1964). All results were expressed in µmol (g dry wt)⁻¹ and are the mean of three samples. The percentage recovery for each metabolite was measured by adding known quantities to the acidified cell suspension. Values of between 83·1 ± 5·3% for ATP and 103·5 ± 6·3% for 6-phosphogluconate were obtained.

Chemicals. All enzymes, intermediates and co-enzymes used in these assays were obtained from Sigma; other reagents were of analytical grade from BDH.

RESULTS AND DISCUSSION

Characterization of fermentation

Continuous cultures were successfully established using control, low nitrogen and low phosphate media. Details of the control fermentation have been published elsewhere (Franco, 1980; Berry et al., 1981) and resemble those published by other workers (Fiechter et al., 1981). In the low nitrogen and phosphate treatments, the yield of yeast was between 0·4 and 0·45 g (g glucose)⁻¹ at dilution rates below 0·2 h⁻¹. However, at higher dilution rates, the level of ethanol in the medium increased and the cell yield indicated a transition to fermentative metabolism (Fig. 1). The absence of glucose in the medium at lower dilution rates indicates that glucose was limiting at these dilution rates even when the levels of phosphate and ammonium were lowered. The maintenance energy of the aerobic glucose-limited chemostat culture was determined at 0·011 g glucose (g dry wt biomass)⁻¹ using the method of Pirt (1975). The values for nitrogen- and phosphate-depleted samples were 0·005 and 0·011 g glucose (g dry wt

biomass)⁻¹, which correspond to dilution rates of 0.0085 and 0.009 h⁻¹, respectively. During the fermentation with phosphate-depleted medium, the yeast acquired a pink pigmentation. Formation of a pink pigment is characteristic of disordered purine metabolism in which the yeast loses its ability to convert hypoxanthine to the riboside in the absence of biotin (Chamberlain et al., 1954; Ahmad et al., 1961). Since phosphorylation steps are essential for this pathway of purine biosynthesis, it appears that the low level of phosphate disrupts the pathway and stimulates the formation of the characteristic pigment.

Levels of intermediates: adenine nucleotides and energy charge

The concentration of intermediates was determined in triplicate at intervals once the steady state had been established. The percentage recovery of metabolites was also determined and recoveries of between 83 and 100% were obtained for all the intermediates studied (Franco, 1980). The values obtained for cellular ATP, up to 15 μmol (g dry wt)⁻¹ are as high as those reported previously in yeast (Chapman & Atkinson, 1977) and indicate that the extraction and fixation technique was rapid enough to prevent significant changes in the level of intermediates during the extraction (Weibel et al., 1974).

The levels of ATP, ADP and AMP were determined and the energy charge was calculated using the method of Atkinson & Walton (1967). In the glucose controls, the level of ATP decreased with increasing dilution rate when the yeast was grown aerobically (Fig. 2). However, it increased again at higher dilution rates, when ethanol fermentation occurred. The levels of ADP and AMP increased, reaching a maximum at the same dilution rate that gave minimum ATP values. A similar pattern was observed when low nitrogen medium was used. However, in the low phosphate medium, ADP and AMP levels were lower and did not show any increase at higher dilution rates (Fig. 2).

The energy charge varied only between 0.7 and 0.9 and the much lower values of energy charge which have been reported in yeast, especially in fermentative conditions (Ball & Atkinson, 1975), were not observed in these experiments. Although ethanol fermentation occurred at higher dilution rates the fermentations were aerobic throughout and probably maintained some mitochondrial activity (see below). The variation of energy charge with dilution rate showed a similar pattern in the control and low nitrogen media, with a low value being observed with the onset of fermentative metabolism and the lowest ATP value. This pattern was not, however, observed in low phosphate medium in which the energy charge remained constant.
The level of adenine nucleotides is subject to very complex regulatory processes (Atkinson, 1977). In *Escherichia coli* the energy charge remains constant over a wide range of growth rates and the higher levels of ATP are observed at the highest growth rates (for a review see Chapman & Atkinson, 1977). However, Forrest (1965) considered that the highest levels of ATP occurred in maintenance conditions when the demand for energy for growth was at a minimum. The results we have presented in yeast appear to indicate that the lowest values of ATP and energy charge are associated with the period of highest aerobic growth rates. It should be emphasized, however, that the rate of ATP formation and breakdown is very rapid so that the level of ATP is not necessarily a good guide to its rate of production and utilization (Fiechter et al., 1981).

**Intermediates of glycolysis**

The metabolites of the early stages of the Embden-Meyerhof-Parnas pathway were present at high levels at low dilution rates and decreased to undetectable levels at high dilution rates. Their levels increased again, however, at dilution rates at which ethanol fermentation occurred. A similar pattern was observed with the nitrogen- and phosphate-depleted media (Fig. 3). The overall level of these intermediates was higher in cells grown in the low nitrogen medium; in particular the level of glucose 6-phosphate was high. Since both low nitrogen levels and low dilution rates have been reported to create conditions which are associated with glycogen accumulation (Kuenzi & Fiechter, 1969, 1972), high levels of glucose 6-phosphate and fructose 6-phosphate would be anticipated in such conditions. The mass action ratio of phosphoglucone isomerase at a dilution rate of 0.0136 h⁻¹ in the control experiments was calculated as 0.51, which is above the equilibrium value of 0.28 and is indicative that gluconeogenesis is indeed occurring in these conditions.

In the control medium, the level of 6-phosphogluconate displayed an inverse relationship with glucose 6-phosphate, suggesting that a major part of the glucose 6-phosphate is directed to the pentose phosphate pathway. The proportion of glucose entering the pentose phosphate pathway was reported to increase with dilution rate because of the increased demand for NADPH for biosynthetic activity (Mian et al., 1974; Neijssel & Tempest, 1976). Fructose 6-phosphate, fructose 1,6-diphosphate and the combined concentrations of dihydroxyacetone phosphate and...
Levels of intermediates in *S. cerevisiae*

Fig. 3. Concentration of selected intermediates of the EMP and pentose phosphate pathways in yeast grown at different growth rates in continuous culture using control medium (▲), low nitrogen medium (○) and low phosphate medium (●). Units are μmol (g dry wt)^{-1}. (a) Glucose 6-phosphate, (b) fructose 6-phosphate, (c) fructose 1,6-diphosphate, (d) 6-phosphogluconate and (e) the combined concentration of dihydroxyacetone phosphate (DHAP) and glyceraldehyde phosphate (GP).

Glyceraldehyde phosphate showed a similar profile to that of glucose 6-phosphate in each of the three series of experiments.

The depletion of intermediates before triose in the Embden–Meyerhof–Parnas pathway at a dilution rate which gives the maximum rate of aerobic growth before ethanol production occurs, indicates that the onset of ethanol fermentation is not induced by the accumulation of one of these intermediates. It appears more probable that the depletion of one of these glycolytic intermediates could be important in the transition to fermentative respiration. However, this transition occurred at somewhat different dilution rates when different media were used, indicating that factors other than glucose feed rate influence this transition. In fact, by careful adaptation of the cells very high aerobic growth rates can be achieved with bakers' yeast (Barford & Hall, 1979).

The variation in the levels of 2-phosphoglycerate, phosphoenolpyruvate and pyruvate was complex (Fig. 4). In the low nitrogen and low phosphate media the pattern resembled that of the other glycolytic intermediates, being high at low dilution rates and during fermentative growth and at a minimum during the transition phase. The level of these three intermediates in the glucose controls was somewhat lower and did not vary much at different aerobic growth rates,
that is up to a dilution rate of 0.16 h⁻¹, but did exhibit an increase during the period of ethanol formation above this dilution rate. The high level of pyruvate and associated intermediates during ethanol fermentation could be expected since pyruvate decarboxylase in the yeast has been reported to have a higher $K_m$ than the pyruvate dehydrogenase enzyme (Oura 1974).

**Intermediates of tricarboxylic acid and glyoxylate cycles**

The levels of citrate and oxalacetate increased with increasing dilution rate until the onset of ethanol formation, when they began to decrease. However, these intermediates persisted at a lower level in conditions which were sufficiently catabolite-repressed to form ethanol in aerobic conditions (Fig. 4). Since these results were obtained in cells grown in steady state conditions, they indicate that conditions can be established in which ethanol fermentation and tricarboxylic acid cycle functions are both present. The supply of oxygen is essential for the formation of several tricarboxylic acid cycle enzymes. Aconitase and succinate dehydrogenase for example have been reported to be produced in aerobic glucose-repressed conditions but not in anaerobic glucose-repressed conditions (Wales et al., 1980).

Depletion of phosphate and nitrogen caused only minor changes in the level of tricarboxylic acid cycle intermediates. However, whereas the level of glyoxylate remained low in the control
and nitrogen-depleted media, it increased dramatically in the low phosphate medium. This increase may be attributable to the need for ATP and GTP for the conversion of oxalacetate to phosphoenolpyruvate during gluconeogenesis. Shortages of ATP and GTP could cause malate to accumulate and this in turn would lead to an accumulation of glyoxylate and other intermediates of the glyoxylate cycle.

One purpose of studying the physiology of industrial micro-organisms is to identify the metabolic conditions which direct most of the available nutrients into the desired product. The levels of selected intermediates of the Embden-Meyerhof-Parnas pathway, the pentose phosphate pathway, the tricarboxylic acid cycle and glyoxylate cycle are clearly influenced by both the dilution rate and the level of nitrogen and phosphate in the medium. In this study, yeast grown in twenty-one steady states which differed in either dilution rate or medium composition were investigated. In no two steady states were the levels of all the intermediates identical. So it is therefore possible to identify each one as a unique metabolic state. These metabolic states are not adequately described by the available terminology such as exponential phase or maintenance phase cells. The measurement of selected intermediates provides a valuable technique to identify and describe the growth of cells in different physiological states. We would propose from these studies that the levels of glucose 6-phosphate, 6-phosphogluconate, pyruvate, citrate and glyoxylate are valuable key indicators, whereas the levels of glyceraldehyde phosphate, dihydroxyacetone phosphate, 2-phosphoglyceric acid and oxalacetate are less useful.

The measurement of intermediates also offers a sensitive technique for studying changes in the physiological response of organisms to the environment and may be more informative than the measurement of enzyme levels in such studies (Harder & Dijkhuizen, 1983). In the formation of baker's active dried yeast the final stages of the fermentation are very critical. The use of levels of intermediates to monitor this phase of the fermentation could give improved control.

C. M. M. F. would like to thank Distillers Company (Yeast) Ltd for support throughout this work.
