Decreased Particulate NADH Oxidase Activity in *Bacillus subtilis* Spores After Polymyxin B Treatment

By KUNIO TOCHIKUBO,* YOKO YASUDA AND SATOSHI KOZUKA

Department of Microbiology, Nagoya City University Medical School, Nagoya, Aichi 467, Japan

(Received 15 May 1985; revised 27 August 1985)

The activities of several enzymes of polymyxin B-treated dormant and germinated spores of *Bacillus subtilis* were examined. The particulate NADH oxidase of the antibiotic-treated spores showed considerably lower specific and total activities compared with those of untreated ones. The specific and total NADH oxidase activities of untreated spores increased 12- and 15-fold respectively during germination, whereas increases during germination of polymyxin B-treated spores were inhibited. The specific and total activities of particulate NADH cytochrome c reductase of dormant spores were decreased by polymyxin B treatment in almost the same proportion as those of the particulate NADH oxidase. The specific activity of NADH dehydrogenase of dormant spores remained unchanged after antibiotic treatment but the total activity fell considerably. The activities of other enzymes examined were similar for untreated dormant and germinated spores and antibiotic-treated spores. The respiration of polymyxin B-treated dormant spores was inhibited at the same time as the start of germination. Morphologically, polymyxin B-treated dormant spores lost a laminar structure of the cortex and details of the spore protoplast. The inhibitory mechanism of particulate NADH oxidase activity of polymyxin B-treated dormant spores is discussed.

**INTRODUCTION**

Cyclic polypeptide antibiotics such as polymyxin B, colistin and gramicidin S, and aminoglycoside antibiotics such as streptomycin, kanamycin and gentamicin bind to the dormant spores of *Bacillus subtilis*, inhibit outgrowth or vegetative growth after germination, and consequently act as sporocidal or sporostatic agents under certain limited conditions (Tochikubo, 1978; Tochikubo et al., 1981). Morphological changes and macromolecular synthesis during germination, outgrowth, and vegetative growth of the dormant spores treated with the above antibiotics have been investigated in detail (Hayakawa et al., 1981). The electrophoretic mobilities of antibiotic-treated dormant spores have confirmed that cyclic polypeptide and aminoglycoside antibiotics bind at least to the spore coat (Tochikubo, 1978; Tochikubo et al., 1981). However, the inhibitory mechanism for outgrowth and vegetative growth, including the mode of penetration of antibiotics, has not yet been clarified. In order to examine this problem, the activities of some enzymes including particulate NADH oxidase of polymyxin B-treated dormant spores were examined. This report describes the correlation between low particulate NADH oxidase activity and inhibited outgrowth of polymyxin B-treated dormant spores.

**METHODS**

*Bacterial strain, germination and other procedures.* Spores of *B. subtilis* PCI 219 were used in this study. Spore preparations and treatment with polymyxin B and colistin were carried out as previously described (Tochikubo et al., 1981). Antibiotic-treated dormant spores at about 5·1 × 10⁹ spores ml⁻¹ were incubated with shaking at 37°C for 2 h in 20 mM-sodium/potassium phosphate buffer (pH 7·2) containing 20 mM-L-alanine, washed five times.

*Abbreviation:* DCIP, 2,6-dichlorophenolindophenol.
with the same buffer, and used as antibiotic-treated germinated spores. Polymyxin B-treated dormant spores were incubated at 37 °C for 2 h in sterile 100 mM-CaCl₂ solution (about 3-1 x 10⁸ spores ml⁻¹, final concentration), washed five times with sterile 20 mM-phosphate buffer (pH 7.2), and used as polymyxin B- and CaCl₂-treated dormant spores. Subsequently, these spores were also germinated in 20 mM-phosphate buffer (pH 7.2) containing 20 mM-L-alanine. Untreated dormant spores (about 5-1 x 10⁸ spores ml⁻¹) were germinated as described above in the presence of 64 μg polymyxin B ml⁻¹ or 100 μg chloramphenicol ml⁻¹.

Preparation of soluble and particulate fractions. A 10 ml sample of a thick spore suspension (about 10¹¹ spores ml⁻¹ in 50 mM-phosphate buffer, pH 7.5), together with 10 g 0-25 to 0-45 mm diameter glass beads, were treated in a 20-kc sonic oscillator (Kubota Insonator Model 200 M) at 2-4 °C at 1-4 A and at 160 W for 30 min for dormant spores and for 10 min for germinated spores. The broken cell suspension was centrifuged at 10700 g for 30 min at 4 °C. The supernatant was centrifuged at 100000 g for 3 h at 4 °C and separated into soluble and particulate fractions; for dormant spores the dipicolinic acid was removed by freezing before ultracentrifugation (Tochikubo & Yasuda, 1983). The particulate fraction obtained by ultracentrifugation was suspended in a small volume of 50 mM-phosphate buffer (pH 7.5). Dormant spores were also sonicated in the presence of various concentrations of polymyxin B dissolved in 50 mM-phosphate buffer (pH 7.5) and soluble and particulate fractions prepared as described above.

Enzyme assays. Particulate NADH oxidase and soluble NADH oxidase (EC 1.6.99.2) were assayed at 37 °C by measuring the decrease in absorbance at 340 nm of NADH as previously described (Tochikubo, 1971; Tochikubo, 1974); 0.3 μmol flavine mononucleotide was added to the assay cuvette containing soluble NADH oxidase. The activity of particulate NADH oxidase was also measured after standing at 0 °C for 4 h in the presence of various concentrations of polymyxin B. NADH dehydrogenase (EC 1.6.99.3) activity was followed spectrophotometrically at 37 °C and at 600 nm. The test system contained 1 μmol 2,6-dichlorophenolindophenol (DCIP), 0.5 μmol KCN, 0.6 μmol NADH, 300 μmol phosphate buffer (pH 7.5), and 0-01 to 0-05 ml sample. The volume was made up to 3-0 ml in the cuvette (1 cm light path) by the addition of deionized water and the reaction was initiated by the addition of NADH. NADH cytochrome c reductase (EC 1.6.99.3) activity was measured at 37 °C and at 550 nm in the same manner as NADH dehydrogenase except that the assay cuvette contained 0-1 μmol cytochrome c in place of DCIP. Alanine dehydrogenase (EC 1.4.1.1) and glucose-6-phosphate dehydrogenase (EC 1.1.1.49) were assayed at 37 °C by measuring NADH and NADPH formation at 340 nm, respectively, as previously described (Nitta et al., 1974; Tanahashi et al., 1976); for glucose-6-phosphate dehydrogenase, 0-1 μmol MgCl₂ was added to the assay cuvette. The activity of alkaline phosphatase (EC 3.1.1.1) was measured according to the method of Glenn & Mandelstam (1971). Enzyme solution (0-05 ml) was added to 0-6 ml 25 mM-borate/NaOH buffer (pH 10.0) containing p-nitrophenyl phosphate and incubated at 37 °C. After colour development, 3-0 ml 0-02 M-NaOH was added to stop the reaction and the molar absorption at 410 nm was measured. For catalase (EC 1.11.1.6) enzyme solution (0-05 ml) was added to 0-6 ml 25 mM-phosphate buffer (pH 7.2) containing 1-5% (v/v) H₂O₂ and incubated at 37 °C. After incubation, 3-0 ml 0-66 mM-H₂SO₄ was added to stop the reaction and the decrease in absorbance at 250 nm of H₂O₂ was measured (Chance & Maehly, 1960).

The following molar absorption coefficients were used: 6.22 mM⁻¹ cm⁻¹ at 340 nm for NADH and NADPH; 21 mM⁻¹ cm⁻¹ at 600 nm for DCIP, and 19 mM⁻¹ cm⁻¹ at 500 nm for cytochrome c. Each activity was calculated from the linear portion of the time course immediately after the reaction was started.

Protein was determined by the Lowry method.

Microbiological assay of polymyxin B. The polymyxin B released from the antibiotic-treated dormant spores during germination or in CaCl₂ solution was measured quantitatively by an antibiotic assay, using the spores of B. subtilis as a test organism. A 0-2 ml sample of the spore suspension (about 10⁷ spores ml⁻¹) was added to 19-8 ml sterile streptomycin agar (Difco), and this was poured into a sterile Petri dish. After solidification, four cups per plate were cut out with a hard steel punch (outside diameter, 8-6 mm). Polymyxin B-treated dormant spores were incubated at 37 °C for 2 h in heart infusion broth, in 20 mM-phosphate buffer (pH 7.2) containing 20 mM-L-alanine, and in 100 mM-CaCl₂ solution, and centrifuged to remove the spores. The supernatant fluid was filtered through a Millipore membrane filter and used as test solution. Polymyxin B dissolved in heart infusion broth, in 20 mM-phosphate buffer (pH 7.2) or in 100 mM-CaCl₂ solution, diluted by a twofold serial dilution method, was used as a standard solution. A 0-15 ml sample of the test or standard solution was pipetted into a cup. After standing at 4 °C for 15 h to allow diffusion of polymyxin B, the plate was incubated at 37 °C for 8 h. The diameter of an inhibitory zone on the surface of the medium was measured with a needle-point caliper.

The amount of polymyxin B in the soluble fractions of polymyxin B-treated dormant and germinated spores, polymyxin B- and CaCl₂-treated dormant spores, and dormant spores sonicated in the presence of various concentrations of polymyxin B was measured as described above. In this case antibiotic dissolved in 20 mM-phosphate buffer (pH 7.2) was used as the standard solution.

Respiration measurement. Untreated, polymyxin B-treated or polymyxin B- and CaCl₂-treated dormant spores were suspended in 50 mM-phosphate buffer (pH 7.2) to give about 5-6 x 10⁵ spores ml⁻¹. A 3-6 ml sample of the spore suspension was saturated with O₂ by gently bubbling air through the solution. Monitoring of O₂
consumption was started at the same time as the initiation of germination by the addition of 3 μmol L-alanine. O₂ consumption was determined at 37 °C in a stirred cell suspension with a Fieldlab oxygen analyser (Beckman Instruments) in the presence and absence of 0.4 μmol NADH. The rate of O₂ consumption was continually monitored up to 120 min and plotted as μmol O₂ (10⁶ spores)⁻¹ ml⁻¹ consumed at the indicated time in Fig. 2(b).

**Electron microscopy** Dormant spores were fixed by the triple-fixation method with a sequential application of 5% (v/v) glutaraldehyde, 1% (w/v) osmium tetroxide (OsO₄), and 2% (w/v) potassium permanganate as previously described (Kozuka & Tochikubo, 1983) and suspended in molten 2% (w/v) agar. After solidification, the agar was cut into 1 mm cubes. The agar cubes were dehydrated by passage through an ethanol series, substituted by n-butyl glycidyl ether, and embedded in Quetol 653 (Kushida, 1980). Germinated spore samples were prefixed in 2.5% (v/v) glutaraldehyde for 3 h at 4 °C and centrifuged at 1500 g. The pellet was suspended in 1 ml 1% (w/v) OsO₄ and 0.1 ml tryptone medium (Difco) (Kellenberger et al., 1958) and was fixed overnight at room temperature. After washing with Kellenberger buffer (Kellenberger et al., 1958), the cell pellet was fixed in 0.5% (w/v) uranyl acetate and suspended in molten 2% (w/v) agar. The agar was cut into 1 mm cubes and treated as described above. Sections were cut on a Porter-Blum MT ultramicrotome, stained with 6% (w/v) uranyl acetate and Reynolds lead citrate (Reynolds, 1963), and examined in a JEOL JEM-200CX electron microscope at an accelerating voltage of 200 kV.

**Chemicals.** NAD, NADP, NADH and glucose 6-phosphate were purchased from Boehringer-Mannheim. Crystalline cytochrome c, prepared from Candido krusei, was purchased from Sankyo, polymyxin B sulphate from Sigma, DCIP and OsO₄ from Merck, and Quetol 653 from Nisshin EM. All other chemicals were of the finest grade.

**RESULTS**

**Enzyme activities of antibiotic-treated dormant and germinated spores**

The activities of several enzymes were examined to elucidate the effect of polymyxin B and colistin treatment on dormant and germinated spores. The particulate NADH oxidase of untreated dormant spores showed high specific and total activities, which increased 12- and 15-fold respectively during germination (Table 1). Polymyxin B treatment decreased the specific and total NADH oxidase activities of dormant spores by 70 and 50%, respectively. The specific and total NADH oxidase activities of polymyxin B-treated germinated spores increased to about three and six times those of the corresponding dormant spores and their values were similar to those of untreated dormant spores (Table 1). Treatment with colistin also resulted in a decrease in the specific and total NADH oxidase activities of dormant and germinated spores, but the extent of inhibition was less than that due to polymyxin B treatment.

Calcium treatment after exposure to polymyxin B did not restore either specific or total enzyme activities of dormant spores whereas those of germinated spores were almost completely restored (Table 1).

Spores germinated in the presence of polymyxin B had almost the same specific and total activities of particulate NADH oxidase as those of polymyxin B-treated germinated spores (Tables 1 and 2). The specific and total activities of the spores germinated in the presence of chloramphenicol were about 84 and 85% of those of untreated germinated spores, respectively (Table 2).

When the particulate fractions from untreated spores were incubated at 0 °C for 4 h in the presence of polymyxin B, the activity of particulate NADH oxidase fell to a similar value for both dormant and germinated spores as the concentration of antibiotic increased (Fig. 1).

The specific and total activities of alkaline phosphatase in the particulate fraction of polymyxin B- and colistin-treated dormant spores were lower than those of untreated ones, but in germinated spores the enzyme showed almost similar specific and total activities regardless of polymyxin B or colistin treatment (Table 1).

The specific and total activities of catalase, NADH oxidase, alanine dehydrogenase and glucose-6-phosphate dehydrogenase in the soluble fractions of dormant and germinated spores exhibited little or no differences after polymyxin B or colistin treatment except that the soluble fraction from polymyxin B- and colistin-treated germinated spores had about one-half the specific and total activities of alanine dehydrogenase compared with that of untreated germinated spores (Table 3).

Comparison of particulate NADH oxidase, NADH dehydrogenase and NADH cytochrome c reductase activities

The extent of the decrease in specific and total activities of NADH oxidase in the particulate fraction of polymyxin B-treated dormant spores corresponded more to that of the specific and total activities of NADH cytochrome c reductase than to that of NADH dehydrogenase (Table 4). The same result was obtained also with polymyxin B- and CaCl₂-treated dormant spores (Table 4), with dormant spores sonicated in the presence of 7 or 10 mg polymyxin B (Table 4), and with polymyxin B-treated germinated spores (data not shown). The specific activity of NADH dehydrogenase of dormant spores was not significantly affected by polymyxin B treatment (Table 4).

As can be calculated from Table 4, the protein content in the particulate fraction of polymyxin B-treated dormant spores was considerably lower than that of untreated spores and the protein content of the particulate fraction of dormant spores sonicated in the presence of polymyxin B decreased as the concentration of the antibiotic was increased.

Quantity of polymyxin B in the soluble fraction

A microbiological assay was carried out to investigate the total amount of polymyxin B released during sonication into the soluble fractions of polymyxin B- and polymyxin B- and CaCl₂-treated dormant spores and polymyxin B-treated germinated spores. Whereas about 860 μg polymyxin B (which was similar to that of the dormant spores sonicated in the presence of 10 mg polymyxin B) were released into the soluble fraction of polymyxin B-treated dormant spores.

spores, no detectable concentration of the antibiotic was released from polymyxin B- and CaCl$_2$-treated ones. The soluble fraction of polymyxin B-treated germinated spores contained about 290 µg polymyxin B. When dormant spores were sonicated in the presence of various concentrations of the antibiotic, no detectable concentration of antibiotic was present in the soluble fractions from dormant spores sonicated at ≤ 5 mg polymyxin B.

Quantitative analysis of polymyxin B released during germination and by treatment with CaCl$_2$

The amount of antibiotic removed from polymyxin B-treated dormant spores during germination and by treatment with CaCl$_2$ was determined. Approximately 2.1 × 10$^8$ spores
Table 4. Specific and total activities of NADH oxidase, NADH dehydrogenase and NADH cytochrome c reductase in the particulate fractions of polymyxin B-treated and polymyxin B- and CaCl₂-treated dormant spores and dormant spores sonicated in the presence of various concentrations of polymyxin B

Specific activity is expressed as nmol NADH oxidized, nmol 2,6-dichlorophenolindophenol reduced or nmol cytochrome c reduced min⁻¹ (mg protein)⁻¹. Total activity is expressed as nmol NADH oxidized, nmol 2,6-dichlorophenolindophenol reduced or nmol cytochrome c reduced min⁻¹ per 10¹² spores sonicated. Each value represents the mean of two determinations. Numbers in parentheses show percentage of activity expressed as activity of polymyxin B-treated and polymyxin B- and CaCl₂-treated dormant spores and dormant spores sonicated in the presence of polymyxin B divided by activity of untreated spores.

ml⁻¹ in heart infusion broth or in 100 mM-phosphate buffer (pH 7.2) containing 20 mM-L-alanine (the physiological germinant for B. subtilis spores) released no detectable concentration of polymyxin B, but in 100 mM-Tris/HCl buffer (pH 7.5) containing 100 mM-CaCl₂ about 3.3 μg ml⁻¹ was released. However, this concentration was about one-quarter of the minimum inhibitory concentration (MIC; 12.5 μg ml⁻¹; Tochikubo et al., 1981) for the same number of dormant spores. When 2.4 times the number of polymyxin B-treated dormant spores (5.1 × 10⁸ spores ml⁻¹) were incubated in heart infusion broth or in 20 mM-L-alanine, 5.3 and 6.1 μg polymyxin B ml⁻¹ were released. These values represent one-quarter to one-fifth of the MIC (25 μg ml⁻¹) for the same number of dormant spores. In 100 mM-CaCl₂ solution they released 10 μg polymyxin B ml⁻¹, which was less than one-half of the MIC.

Respiration during germination of polymyxin B-treated dormant spores

Although the germination rate was slightly stimulated compared with untreated dormant spores (Fig. 2a), the respiration of polymyxin B-treated dormant spores was inhibited at the same time as the start of germination and the inhibition of respiration after 120 min was more than 90% (Fig. 2b). Subsequent treatment with CaCl₂ before germination restored the respiration of polymyxin B-treated dormant spores to that of untreated spores (Fig. 2b). Similar results were also obtained in the absence of NADH (data not shown).

Morphologic changes of polymyxin B-treated dormant and germinated spores

The majority of untreated dormant spores demonstrated a laminar cortex and a spore protoplast with a clear roundish germ cell wall and granules (Fig. 3a), whereas a considerable number of polymyxin B-treated dormant spores lost structural details of the cortex and the spore protoplast, and moreover, the latter was irregular in form (Fig. 3b). Insufficient infiltration of resins was also observed.

The untreated germinated spores 2 h after incubation in 20 mM-L-alanine solution showed a thinness of the spore coat, a diminution in size of the cortex, a swollen core, a cell wall, some
Effect of polymyxin B on B. subtilis spores

Fig. 2. Time course of L-alanine-initiated germination (a) and respiration during germination (b) of polymyxin B-treated dormant spores. Germination experiments were done by incubation of dormant spores (about $2 \times 10^7$ cells ml$^{-1}$) at 37°C in 3 ml 50 mM phosphate buffer (pH 7.2) containing 3 μmol L-alanine. Germination was measured by loss of optical density of the spore suspension and is expressed as a percentage of the reduction in OD$_{540}$ determined with a Bausch & Lomb Spectronic 20A spectrophotometer by the method of Itachisuka et al. (1955). See text for details of respiration measurement. ●, Untreated dormant spores; ○, polymyxin B-treated spores; ▲, polymyxin B- and CaCl$_2$-treated spores.

mesosomes and DNA fibrils (Fig. 4a). Fig. 4(b) shows a thin section of the germinated spores derived from polymyxin B-treated dormant spores after incubation for 2 h in 20 mM-L-alanine solution. The spore core appears irregular in form and the thin cell wall was detached from the cytoplasmic membrane in some places. Moreover, the cytoplasm was densely homogeneous and not granular, and the nuclear material was not visible. These features are in agreement with those of the germinated spores derived from polymyxin B-treated dormant spores after incubation for 3 and 24 h in heart infusion broth (Hayakawa et al., 1981).

Electron micrographs of the spores germinated in the presence of chloramphenicol and polymyxin B resembled those of untreated germinated spores and polymyxin B-treated ones, respectively (data not shown).

DISCUSSION

The basic polypeptide antibiotic polymyxin B kills bacteria by interaction with the cytoplasmic membrane (Few, 1955; Newton, 1956; Storm et al., 1977). The mode of action may be an irreversible breakdown of the permeability barrier of the membrane (Imai et al., 1975).

The activity of particulate NADH oxidase of polymyxin B-treated dormant spores was considerably lower when compared with that of untreated ones, and the antibiotic treatment inhibited the remarkable increase in particulate NADH oxidase activity during germination (Table 1) as well as growth after germination (Tochikubo et al., 1981; Hayakawa et al., 1981). Although the enzyme activity of polymyxin B- and CaCl$_2$-treated dormant spores was inhibited to the same extent as that of polymyxin B-treated spores (Tables 1 and 4), they recovered the growth ability after germination (Tochikubo et al., 1981). It is therefore necessary to distinguish between the effect of polymyxin B on enzyme activity and that of the antibiotic on growth after germination. Polymyxin B treatment clearly has direct or indirect effects upon the membranous structure of dormant spores which is the site of the electron transport chain and oxidative phosphorylation. At least two possibilities can be considered with regard to the inhibitory mechanism of particulate NADH oxidase activity of polymyxin B-treated dormant spores. The
The first possibility is that polymyxin B not only binds to the spore coat (Tochikubo et al., 1981) but can also penetrate to the inner cytoplasmic membrane, leading to the inhibition of respiration. However, since treatment of polymyxin B-treated dormant spores with CaCl₂ reversed the inhibitory effect of the antibiotic on growth (Tochikubo et al., 1981) and the activity of particulate NADH oxidase from their germinated spores was almost the same as that from untreated spores (Table I), it is considered that an irreversible breakdown of the cytoplasmic...
membrane did not occur by treatment with the antibiotic. Therefore the antibiotic is not able to reach the cytoplasmic membrane of dormant spores. The second possibility is that interaction of polymyxin B with the outer pericortex membrane of dormant spores can affect the cytoplasmic membrane in some way to inhibit respiration without binding directly to the membrane. In *Escherichia coli* and *Pseudomonas aeruginosa* perturbation of the outer membrane structure by immobilized polymyxin can indirectly affect bacterial growth and respiration without direct
interaction of the antibiotic with the cytoplasmic membrane (LaPorte et al., 1977). The existence of an outer membrane in the dormant spores of *Bacillus megaterium* has been demonstrated biochemically since the isolated outer integument contains cytochromes, electron transport enzymes and polypeptides (Crais-Lighty & Ellar, 1980) and by the morphological observation of variant spores lacking exosporium (Koshikawa et al., 1984). Accordingly, the second possibility seems most likely. The unclear structure and irregular form of the protoplast of polymyxin B-treated dormant spores (Fig. 3b) may be due to unsufficient infiltration of fixatives caused by perturbation of the outer membrane. In this case, although the disorder of the outer membrane by polymyxin B does not seem to be recoverable, the cytoplasmic membrane appears to bear the antibiotic damage because of complete reversion of both particulate NADH oxidase activity (Table 1) and O₂ consumption (Fig. 2h) during germination of polymyxin B- and CaCl₂-treated dormant spores.

Addition of CaCl₂ to polymyxin B-treated dormant spores reverses the electrophoretic mobility within the normal range by releasing the antibiotic bound to the spore coat surface (Tochikubo et al., 1981). Since 10 µg polymyxin B is released from about 5.1 × 10⁸ spores, about 20 mg polymyxin B will be released from 10¹² polymyxin B-treated dormant spores by treatment with 100 mM-CaCl₂. No detectable concentration of the antibiotic was found in the soluble fraction of polymyxin B- and CaCl₂-treated dormant spores and therefore the total amount of the antibiotic binding to 10¹² spores after CaCl₂ treatment is ≤ 5 mg. It seems probable that about 20 mg polymyxin B binds to the spore coat and can be easily dissociated by treatment with CaCl₂, whereas a small quantity (5 mg and less) of the antibiotic binds to the outer pericortex membrane and cannot be dissociated by CaCl₂ treatment. Thus the low activity of particulate NADH oxidase of polymyxin B- and CaCl₂-treated dormant spores may be due to the inhibitory effect of a small amount of the antibiotic binding to the outer pericortex membrane.

The low activity of particulate NADH oxidase (Table 1) and the inhibited outgrowth of polymyxin B-treated germinated spores (Tochikubo et al., 1981) could be due to antibiotic released from the spore coat during germination. It seems that germinating spores directly incorporate the released antibiotic into the inside, since about 89% of the polymyxin B-treated dormant spores are not able to form colonies on heart infusion agar plates (Tochikubo et al., 1981) and the respiration of polymyxin B-treated dormant spores was inhibited at the same time as the start of germination (Fig. 2h). The recovery of growth ability of polymyxin B- and CaCl₂-treated dormant spores may be due to the removal of bound antibiotic.

The inhibitory action of polymyxin B on the activity of particulate NADH oxidase may occur during spore fractionation. However, the following two facts support our opinion that inhibition of the enzyme activity by polymyxin B occurs before spore fractionation: (i) in spite of very low specific and total enzyme activities, the soluble fraction of polymyxin B- and CaCl₂-treated dormant spores contained no detectable concentration of the antibiotic; (ii) inhibition of respiration of polymyxin B-treated dormant spores occurred at the same time as the initiation of germination (Fig. 2h). The recovery of growth ability of polymyxin B- and CaCl₂-treated dormant spores are not due to the removal of bound antibiotic.

The decrease in the specific and total activities of particulate NADH oxidase by polymyxin B treatment agreed well with those for NADH cytochrome c reductase activities but not with those for NADH dehydrogenase activities (Table 4). The specific activity of NADH dehydrogenase after polymyxin B treatment was almost in agreement with that of untreated dormant spores, but about 64% of the total enzyme activity was lost (Table 4). This loss originated in the decrease in the protein content from the particulate fraction of polymyxin B-treated dormant spores. If the protein content of the latter is corrected to the same protein content as that of untreated spores in Table 4, 93% of the total enzyme activity was recovered. This suggests that there is little or no decrease in the total activity of NADH dehydrogenase by a specific action of polymyxin B on the enzyme. The site inhibited by the antibiotic in the electron transport chain seems to be between coenzyme Q and cytochrome c.

The protein content of the particulate fraction of polymyxin B-treated dormant spores decreased by approximately one-half compared with that of untreated spores, and sonication of dormant spores in the presence of polymyxin B also decreased the protein content in particulate fractions depending on the antibiotic concentration (Tables 1 and 4). A high concentration of
polymyxin B may therefore damage membranous structures and induce solubilization of membrane-bound proteins during fractionation even at low temperature. The decrease in total activities of particulate NADH oxidase and NADH cytochrome c reductase by polymyxin B treatment is therefore caused both by the decrease in the specific activities of the enzymes and by that in the particulate protein content.

Wilkinson et al. (1977) have reported that a rapid chloramphenicol-resistant activation of certain membrane-bound respiratory chain enzymes occurs in the first 10 min of germination of Bacillus megaterium KM spores. The same phenomenon was observed also with the particulate NADH oxidase of B. subtilis spores (Table 2).

We are grateful to Dr Roy H. Doi, Department of Biochemistry and Biophysics, University of California, Davis, USA, for his review and valuable criticism of the manuscript.
