Phenotypic Characteristics of a Slow-growing, Nongerminating Variant of *Candida albicans*

By DEXTER H. HOWARD,* MARIE L. ZEUTHEN AND NINA DABROWA

Department of Microbiology and Immunology, UCLA School of Medicine, Los Angeles, California 90024, USA

(Received 9 December 1985)

Some of the phenotypic characteristics of a slow-growing, nongerminating variant of a commonly studied strain of *Candida albicans* are described. The variant arose as a chance isolate. The rate of occurrence was about 0.1% and the reversion rate was about 1 per 10^6 cells. The colony size was typically smaller than that of the parent and the yeast cells tended not to separate from one another so that catenulate strands of cells (pseudohyphae) were formed. Under standard conditions the generation time of the small-colony variant in liquid shake cultures was about twice that of the parental strain. Growth of the variant was suppressed by antimycin A, indicating that the small colony form was not the consequence of a defect in the cytochrome system. The colony size of the variant was not influenced by chlorobenzotriazole, which suggested that adenine metabolism was not involved in the small-colony phenotype. The pseudohyphal growth pattern was not relieved by high concentrations of utilizable carbohydrates, which means the catenulate microscopic appearance of the yeast cells was not simply an exaggeration of the normal growth pattern of isolates of *C. albicans* but more probably represented the growth of a cell-cycle mutant defective at the cell separation step. The cytoplasmic proteins of the variant and the parent were very similar though some unique peptides were displayed by each.

**INTRODUCTION**

*Candida albicans* is a polymorphic, opportunistic, zoopathogenic fungus which grows as a budding yeast (blastoconidia), as a pseudohypha of elongated yeast cells, and as a true, septate hypha (Meyer *et al.*, 1984; Odds, 1979). The true hyphal form of growth is initiated by germination of the blastoconidia (Dabrowa & Howard, 1983; Szaniszlo *et al.*, 1983), and interest in this germination event centres in the developmental biology of the fungus and in the possible role of germ tube formation in the pathogenesis of candidiasis (Ahrens *et al.*, 1983; Brown & Chaffin, 1981; Brummel & Soll, 1982; Cassone *et al.*, 1985; Martin *et al.*, 1984; Manning & Mitchell, 1980; Odds, 1979; Sobel *et al.*, 1984; Szaniszlo *et al.*, 1983).

The search for a differential expression of the genome of *C. albicans* in germination would be facilitated by a comparative study with nongerminating variants (Dahlberg & Van Etten, 1982). Although germ-tube-negative isolates are encountered in the clinical laboratory (Beneke & Rogers, 1980; McGinnis, 1980; Ogletree *et al.*, 1978; Dolan & Ihrke, 1971), the occurrence is often related to the method employed in the test, especially the inoculum size (D. H. Howard, unpublished observations; Martin *et al.*, 1984; Ogletree *et al.*, 1978). Stable nongerminating isolates whose inability to germinate is not related to the methods employed in the germ tube test are fairly uncommon but have been consistently recorded in the literature (see for example Mardon *et al.*, 1969; Ogletree *et al.*, 1978; Torosantucci & Cassone, 1983; Martin *et al.*, 1984). However, such encountered strains are usually single isolates and the germination-competent parent is accordingly unavailable for comparison.

*Abbreviation: SHAM, salicylhydroxamic acid.*
There have been few efforts to induce nongerminating mutants with mutagenic agents such as UV irradiation (D. Oblack, unpublished observations; Pomes et al., 1985) or nitrosoguanidine (D. H. Howard, unpublished observations). However, naturally occurring nongerminating variants of stock cultures have been recorded. For example, Buckley et al. (1982) reported the isolation of such a variant from strain 3153A of C. albicans. This isolate was one of five such variants from strain 3153A discovered by Buckley and used by Olaiya et al. (1980) in their work on a haploid state in C. albicans. The strain 3153A (MRL 3153 of the Mycology Reference Laboratory, London, UK) is the same as the B311 strain of H. F. Hasenclever (see, e.g., Hasenclever, 1965) and is deposited in the American Type Culture Collection as ATCC 32354. Buckley et al. (1982) reported that the nongerminating variant (labelled B311-V6) occurred at a frequency of 2%. This exceptionally high frequency suggested that strain 3153A might provide nongerminating variants regularly and we investigated this possibility. We did not discover nongerminating variants at the same frequency as did Buckley et al. (1982), but we did isolate a small-colony form which did not germinate in any of the customary media designed to reveal germ tube formation (Dabrowa & Howard, 1983). The colonial size of the variant was a reflection of its slow growth rate; a preliminary characterization of the strain, labelled 3153A-SG, has been published (Dabrowa & Howard, 1984). We now provide a more complete description of its phenotypic characters and compare these characters with those of other small-colony forms of C. albicans recorded in the literature.

The strain 3153A which is the same as B311 (see above) has given rise to another nongerminating variant (PCA-2) in another laboratory (A. Cassone, personal communication). Thus nongerminative variants occur, at least in some strains, with a frequency that makes their isolation relatively easy. Our cumulative experience with the phenotypic characteristics of a number of such variants of 3153A as well as those from other stock cultures will be the subject of another publication.

METHODS

Organisms. Candida albicans strains 300 and 300-SG were used in this study. Strain 300 is ATCC 32354 and has also been identified with the following numbers in various studies: 3153A (Dabrowa & Howard, 1984), B311 (Hasenclever, 1965), and B311-10 (Buckley et al., 1982). Strain 300-SG has been used in a previous study under the number of 3153A-SG (Dabrowa & Howard, 1984). Stock cultures are preserved in the Fungus Collection, University of California, Los Angeles, Calif., USA. Working cultures were maintained on glucose peptone agar in a refrigerator and were subcultured every month.

Media. Glucose peptone agar (GPA) contained 2% (w/v) Bacto Dextrose (Difco), 1% (w/v) Bacto Peptone (Difco), and 2% (w/v) Bacto Agar (Difco). Glucose peptone broth (GPB) had the same constituents without the agar. Yeast Nitrogen Base without amino acids (YNB) was prepared in accordance with the manufacturer’s instructions (Difco). LBC synthetic medium (Lee et al., 1975) consisted of: (NH₄)₂SO₄, 5 g; MgSO₄·7H₂O, 0.2 g; K₂HPO₄, 2.5 g; NaCl, 5 g; glucose, 12.5 g; alanine, 0.5 g; leucine, 1.3 g; lysine, 1 g; methionine, 0.1 g; ornithine, 0.0714 g; phenylalanine, 0.5 g; proline, 0.5 g; threonine, 0.5 g; biotin (Nutritional Biochemicals Corp.), 1 mg; distilled water, 1 litre. The biotin was filter-sterilized and added to the other ingredients after they had been autoclaved at 110 °C for 20 min. Chemicals, including amino acids, were purchased from Sigma, Calbiochem or Eastman Kodak.

Germination assays. The strains were incubated in YNB at room temperature overnight, harvested in distilled water, washed once by centrifugation and resuspended to a concentration of 1 × 10⁷ cells ml⁻¹. The media used to foster germination included: (i) single inducers (L-proline and N-acetylglucosamine) at a concentration of 0.2 mM in 0.033 M-phosphate buffer (pH 7.0); (ii) LBC medium; and (iii) lamb serum (Gibco). About 1 × 10⁶ cells ml⁻¹ were incubated in 1 ml of each medium for 3 h at 37 °C. The tubes were agitated gently on a Multipurpose Rotator, model 150 (Scientific Industries, Inc.). A loopful of the cells was removed from each of the media, placed on a glass slide and examined microscopically. The percentage of cells with germ tubes was determined by counting 100 cells.

Isolation of the variant strain 300-SG. Cultures of strain 300 were grown overnight at room temperature in YNB. The cells were harvested by centrifugation, washed three times in distilled water and plated on GPA at a level of approximately 100 c.f.u. per plate. Each of the colonies was touched with a sterile toothpick and the adherent cells were transferred to the well of a Micro Test II tissue culture plate (Falcon Plastics: Becton Dickinson) containing LBC medium. The dishes were incubated at 37 °C for 3 h and the contents of each well were examined under the low power of a microscope. Further details are given in Results.
Measurement of growth under standard conditions. Cells of strains 300 and 300-SG were grown in 50 ml YNB or GPB contained in 300 ml side-arm flasks (Belico Glass). Growth was initiated at a cell concentration of about \(5 \times 10^6\) cells ml\(^{-1}\) from an overnight culture incubated at 37 °C (stationary-phase cells). The cultures were grown on a rotary shaker at 37 °C and growth was assessed by measuring density with a Klett-Summerson photoelectric colorimeter.

Growth suppression by respiratory inhibitors. Two inhibitors, antimycin A (Calbiochem) and salicylhydroxamic acid (SHAM) (Aldrich) were tested for their effect on the growth of strains 300 and 300-SG. The inhibitors, dissolved in 100% methanol, were added to GPB and cultures were grown as described in the preceding paragraph. Two flasks were used for each experimental condition as follows: medium alone, medium with 1-5% methanol (final concentration of solvent used to dissolve inhibitors), medium plus 50 \(\mu\)M-antimycin A, medium plus 5 mM-SHAM, and medium plus both antimycin A (50 \(\mu\)M) and SHAM (5 mM). The cultures were grown and monitored as described in the preceding paragraph. Comparisons of the amount of growth in the presence of the inhibitors were made when control cultures (medium and medium with methanol) entered stationary phase.

Colonial characteristics in the presence of chlorobenzotriazole. Cells of the two strains were plated on YNB with 1% (w/v) glucose and chlorobenzotriazole (Aldrich) ranging in concentration from 10\(^{-2}\) to 10\(^{-6}\) M. The colony texture and the microscopic appearance of the cells were recorded.

RESULTS AND DISCUSSION

Isolation of variant, frequency and reversion

In working with strain 300 of \(C.\) albicans, Buckley et al. (1982) recorded that nongerminating variants occurred at a rate of 2%. We tested this strain for the frequency of nongerminating variants. Cells from an overnight culture grown at room temperature in YNB were plated on GPA at about 100 c.f.u. per plate. One thousand individual colonies were each examined in multiwell dishes for their ability to germinate in LBC medium at 37 °C. All of the cells germinated but in the course of the isolation procedures a small-colony form was observed and subcultured for further study. This isolate, designated 300-SG, was a nongerminating variant and has been used in our study on heat-shock proteins (Dabrowa & Howard, 1984). We have not determined its frequency beyond the description just given of one instance from amongst \(10^3\) colonies, but it probably represents a chance observation. It displayed a number of interesting characteristics (e.g. small colony size, nongermination, catenulate arrangement of yeast cells, and stability of morphological characters).

Two hundred individual colonies of strain 300-SG were studied for revertants in multiwell dishes containing LBC medium (see above). Each well contained about 10\(^4\) yeast cells, so approximately \(2 \times 10^6\) cells were observed. Two cells with germ tubes were detected. Thus, reversion occurred at a rate of 1 per \(10^6\) cells. The phenotype of the two variants of strain 300 thus far described is quite different (Buckley et al., 1982; Dabrowa & Howard, 1983, 1984). The reversion rate in strain 300-SG is low and the variant has retained its characteristics for more than three years in our laboratory.

Morphology and germination

The salient features of the microscopic morphology of strain 300 and the variant strain 300-SG are shown in Fig. 1. Microscopic examination of cell suspensions of strain 300 harvested from cultures grown on YNB for 24 h at 23 °C revealed single yeast cells and occasional budding cells. No pseudohyphae or germ tubes were observed in the cell suspensions used as inocula in the studies reported. Yeast cells (blastoconidia) released into LBC medium at
37 °C did not germinate during the first 20 min of incubation. At 40 min very small germ tubes protruded from about 50–60% of the cells. At 60 min most of the cells had germ tubes the same length as the diameter of the mother cell, and by 120 min 90–95% of the cells had produced germ tubes at least twice as long as the diameter of the mother cell (Fig. 1 a). During the same period of incubation at 23 °C, the cells remained as single or budded yeast cells. Incubation of the nongerminating variant strain 300-SG at either 23 °C or 37 °C in LBC medium resulted in yeast cell growth with pronounced formation of pseudohyphae (Fig. 1 b). No germ tubes were observed regardless of the length of the incubation in LBC medium at 37 °C. Cells of strain 300-SG did not germinate when incubated at 37 °C for as long as 24 h in such common inducers as serum, proline-buffer medium and N-acetylglucosamine.
Table 1. Growth characteristics of strains 300 and 300-SG in YNB at room temperature and at 37 °C

About $5 \times 10^6$ cells ml$^{-1}$ were inoculated into YNB with 1% glucose initially. Growth was monitored by measurements in a Klett-Summerson photoelectric colorimeter.

**Colony morphology**

The appearance of colonies of strain 300 and strain 300-SG is shown in Fig. 2. The colony texture of the nongerminating variant was rough but not nearly as strikingly so as for the UV-induced morphological mutant described by Pomes et al. (1985). The appearance of our small-colony variant was not distinctive enough to allow detection of sectored colonies among several thousand colonies examined for that attribute.

The small-colony form and the failure to germinate under standard conditions were the two most obvious variations displayed by strain 300-SG. It developed abundant pseudohyphae and chlamydoconidia in corn meal agar and assimilated the carbohydrates characteristic of strains of *C. albicans* (Silva-Hutner & Cooper, 1980).

**Growth under standard conditions**

Growth of strains 300 and 300-SG in YNB with 1% glucose was monitored by measuring optical density. The strains each exhibited a lag phase, an exponential phase and a stationary phase. The durations of each of the growth phases varied somewhat from experiment to experiment; representative results from cultures grown at room temperature and at 37 °C are shown in Table 1. The lag phases of the two strains depended on the temperature of incubation and were consistently longer for the slow-growing variant. The generation times in the exponential phase of growth were prolonged in strain 300-SG and the time required to enter the stationary phase corresponded to the longer lag phase and generation time. Slight differences in the duration of the three phases of growth were observed when GPB was used in place of YNB but the overall behaviour of the two strains was the same. The generation time of strain 300 reported by Buckley et al. (1982) was comparable to that recorded in Table 1 but strain 300-SG was slower growing than B311-V6.

**Growth suppression by antimycin A and SHAM**

Small colony forms that are respiratory-deficient mutants have been described in *Saccharomyces cerevisiae* and *Torulopsis glabrata* (Fincham et al., 1979). A naturally occurring respiratory-deficient strain of *Candida slooffii* has been described (Arthur et al., 1978) and petite mutants of several yeast species might be widespread in environments nonselective for respiratory competence (Arthur et al., 1978). A few examples include *Torulopsis pintolopesii*, *Torulopsis lactis-condensi* and *Schizosaccharomyces japonicus* var. *versatilis*. The petite mutation is reported to be lethal for *Candida albicans* (Alvarez & MacKinnon, 1957; Bulder, 1964a, b), but a petite-like variant with an alternative respiratory pathway has been described (Kot et al., 1976).

Yamaguchi (1974, 1975) reported that the respiratory activity of yeast cells of *C. albicans* declined when they were placed under germinating conditions. Land et al. (1975) also reported repression of respiration in germinating blastoconidia of *C. albicans*. However, Shepherd et al. (1978) and Aoki & Ito-Kuwa (1982) presented data that emphasized that repression of respiration did not play an essential role in yeast cell germination, although there is a difference between yeast and mycelial cells in their ability to display the cyanide-insensitive respiratory pathway.
Table 2. Effect of antimycin A and SHAM on the growth of strains 300 and 300-SG

Growth was determined at 37 °C in YNB with 1% glucose to which was added the indicated solvent and inhibitors. The results represent the amount of growth at the time of entry of control cultures (medium and medium + methanol) into the stationary phase (those times for the experiment recorded were 11 h for strain 300 and 15 h for strain 300-SG). Percentage inhibition of growth over that in the medium + methanol control is given in parenthesis.

* Final concentration of solvent used to dissolve inhibitors.

Respiratory-deficient mutants of Neurospora crassa termed 'poky' have long been known (Brody, 1981). A similar phenotype has been described in a mutant of Arthroderma benhamiae which displayed a defective standard cytochrome system and a functional alternative oxidase pathway (Howard & Dabrowa, 1979). A branched electron transport system consisting of a standard cytochrome system which is inhibited by cyanide and an alternative oxidase system inhibited by SHAM has been demonstrated in Histoplasma capsulatum (Maresca et al., 1979).

Experiments were undertaken to determine whether the small-colony form and delayed growth rates of strain 300-SG were related to a defect in the standard cytochrome or alternative oxidase systems. Inhibition of growth of strains 300 and 300-SG by antimycin A (cytochrome system) and by SHAM (alternative oxidase system) was studied (Table 2). Antimycin A inhibited the growth of both strains. Therefore there was no evidence for a defect in the cytochrome system of strain 300-SG. Both strains displayed a SHAM-sensitive alternative oxidase system. The two inhibitors together almost completely inhibited growth.

Colony characteristics in the presence of chlorobenzotriazole

Bianchi (1961) described a small-colony variant of Candida albicans that occurred naturally in cultures at a frequency of about 1–3%. The colony size was due to a slower growth rate and was not related to any defects in the terminal oxidative enzymes. Several of the benzazoles related in structure to benzimidazole, which is an antagonist of adenine metabolism (Woolley, 1944), caused the small-colony variant to grow more rapidly and thereby to produce colonies comparable in size to the wild-type (Bianchi, 1961). The basic defect in the variant which was relieved by the action of benzoles was not precisely identified by Bianchi (1961) but the similarity of colony size and natural occurrence of the variant led us to test the sensitivity of strain 300-SG to benzazoles.

Plates of YNB with 1% glucose were supplemented with chlorobenzotriazole in the range $10^{-2}$–$10^{-6}$ M. Strains 300-SG and 300 were plated on supplemented and unsupplemented media and incubated at room temperature and 37 °C. There were no detectable differences in the rate of growth of either strain in any of the concentrations of chlorobenzotriazole tested. The colony size of strain 300-SG was again small in comparison with that of strain 300 regardless of the presence of chlorobenzotriazole. Thus the small-colony variant 300-SG is different from the one described by Bianchi (1961).

Growth characteristics at different levels of utilizable carbohydrates

A fringe of pseudohyphae occurs at the periphery of colonies of most isolates of C. albicans incubated for long periods on GPA (Rippon, 1982). Such growth results from the decrease in glucose concentration in the vicinity of the colony and is fostered on media devoid of utilizable carbohydrate (Nickerson & Mankowski, 1953). Ireland & Sarachek (1968) described a small, rough-colony variant of C. albicans. The colonies of the variant became progressively rough during prolonged incubation because of extensive development of pseudohyphae. Supplement-
ing the medium with large amounts of glucose, intermediates of the tricarboxylic acid cycle or any of several amino acids derived biosynthetically from intermediates of oxidative respiration prevented the formation of pseudohyphae by the variant but did not affect the growth rate or colony size. We decided to test the notation that 300-SG might represent a similar sort of mutant because of its slow growth rate and prominent pseudohyphal appearance in mature colonies. Increasing the glucose concentration in GPA from 1% to 10% did not affect the pseudohyphal appearance of strain 300-SG or its growth rate. This same result occurred when 300-SG was cultivated on Harrold's agar, which contains 40% sucrose. These results suggest that the variant may be a cell-cycle mutant defective at the cell separation stage rather than a variant with an exaggeration of the customary pseudohyphal growth form which is suppressible by excess levels of utilizable carbohydrate.

Protein differences between strains 300 and 300-SG

Results of the analysis of the cytoplasmic proteins from strains 300 and 300-SG by sodium dodecyl sulphate-polyacrylamide slab gel electrophoresis have been reported (Dabrowa & Howard, 1984). This comparison has now been extended by two-dimensional O’Farrell gel analysis. The protein patterns produced on the gels from lysates of cells of each of the strains grown at room temperature revealed very few differences. Approximately 205 proteins were resolved and stained on the gels. Two proteins of apparent \( M, 49000 \) and \( 58000 \) were present in strain 300 but not in strain 300-SG whilst one protein of apparent \( M, 25000 \) was found in strain 300-SG but not in strain 300. However, the efficiency of this method of analysis is open to question since measurements of mRNA complexity in Saccharomyces cerevisiae suggest that 4000 different proteins are synthesized (Hereford & Rosbash, 1977). Although the total capacity of \( C. \) albicans to produce different proteins has not been estimated, it is likely to be at least one order of magnitude larger than that detected in our stained gels and thus there is a possibility that some minor strain-specific proteins were not detected. Furthermore, the two-dimensional technique used does not resolve basic proteins. Hence, further work with gradient gels will be needed to resolve possible differences in proteins synthesized by the two strains.

This investigation was supported by Public Health Service grant AI-16252 from the National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD, and from the University Task Force on AIDS, University of California. We are grateful to Mr Heinrich Kolbel and Ms Eufemia Tsui for skilful technical assistance. We thank Ms Lois Howard for her care in preparing the manuscript and Dr Rishab Gupta for consultation on growth curve analysis. This is publication no. 111 of the Collaborative California Universities–Mycology Research Unit (CCU–MRU).
