(Received 9 June 1986; revised 24 September 1986)

Exopolysaccharides (EXPs) of Staphylococcus aureus are associated with virulence in animal models. An EXP from the S. aureus strain Smith diffuse was previously detected in 64.3% of S. aureus clinical isolates. EXP was isolated from culture supernatants of this strain after DNAase, RNAase, phosphodiesterase I and lysostaphin treatment, and was further purified by cation-exchange and molecular-sieve chromatography. Isoelectric focusing revealed a pI of 3.6 for the EXP while the pI of teichoic acid was <2.7. Crossed immunoelectrophoresis with homologous Smith diffuse antisera indicated that the EXP contained two immunological components. A major precipitin line persisted after the antisera had been absorbed with the non-EXP-producing variant strain, Smith compact, while the second component was removed. Tandem immunoelectrophoresis also demonstrated that the EXP was distinct from teichoic acid. The EXP contained 2-amino-2-deoxyglucuronic acid, glucose, mannose and galactose. No fatty acids or nucleic acids were present and total protein content was <2%. Teichoic acid could not be demonstrated in the EXP, thus further substantiating the immunological studies. S. aureus EXP isolated by the present method can be used for further serological and virulence studies.

INTRODUCTION

The Staphylococcus aureus Smith diffuse strain was isolated from a patient with osteomyelitis in 1930 and was not described until 1956 (Smith & Dubos, 1956). The strain attracted laboratory attention because of its unique capacity for causing a lethal peritonitis in mice (Hunt & Moses, 1958). Koenig (1962) later isolated an avirulent variant (Smith compact strain) and demonstrated that the virulence of the Smith diffuse strain was related to the presence of an exopolysaccharide (EXP) that the variant, Smith compact, lacked.

We previously found that 64.3% of clinical S. aureus strains produced an EXP antigenically identical to the S. aureus Smith diffuse strain (West et al., 1985). Because of the common occurrence of the Smith diffuse EXP, we have now developed a method for its isolation free of teichoic acid. Immunological characterization of this preparation has been performed with crossed immunoelectrophoresis, tandem immunoelectrophoresis and isoelectric focusing. Preliminary biochemical analysis has indicated the absence of significant quantities of teichoic acid or peptidoglycan and established the major polysaccharide constituents. This new method for isolating a common S. aureus EXP should prove useful in further serological investigations of S. aureus infections.

METHODS

Materials. Culture media and additives were obtained from Difco, and DNAase (type I), RNAase (type I-AS), phosphodiesterase I and lysostaphin from Sigma. Other equipment and reagents were obtained from the indicated sources or were of reagent or higher grade.

Type strain and production of antisera. The S. aureus Smith diffuse strain and the nonencapsulated variant Smith compact strain were obtained from M. Ann Mely, Vanderbilt University, Nashville, Tenn., USA. Antiserum to the Smith diffuse strain was produced in rabbits (Oeding, 1957). Absorbed antisera were prepared by treating antisera to the Smith diffuse strain with each of the variant Smith strains.

Immunological analysis of bacterial antigens. Analysis was done in gels containing 1% (w/v) agarose (Litex type LSL, Accurate Scientific Co., Westbury, NY) and 4% (w/v) dextran T-70 (Pharmacia) in 0-025 m-barbital/borate buffer (pH 8-6). Counter-immunoelectrophoresis was done in gels containing 3 mm diameter wells 5 mm apart, at a constant current of 15 mA per slide for 60 min. The first dimension of crossed immunoelectrophoresis used a portion of the slide (75 × 15 mm) with migration from cathode to anode at a constant voltage of 120 V for 2 h. For the second phase, a constant voltage of 100 V was applied for 4 h and the remainder of the slide (75 × 35 mm) filled with gel containing 19 µl antiserum cm⁻¹. Tandem immunoelectrophoresis was also used for simultaneous comparison of two antigen preparations.

Isoelectric focusing. The isoelectric point was determined by a preparative technique in Bio-lyte (Bio-Rad) with the appropriate Pharmalyte (Pharmacia) added to a final concentration of 2% (Righetti & Drysdale, 1979). Antigen samples were applied to the middle of the gel and electrophoresed at a constant power of 8–10 W. The gel bed was then divided into 24 sections. The location of the antigens was determined by gel-immunodiffusion of the eluates from each section against the desired antisera.

Preparation of peptidoglycan and teichoic acid. Peptidoglycan was prepared from the S. aureus Smith compact strain as described by Peterson et al. (1978) and Verbrugh et al. (1981). The bacteria were cultured in broth containing 1-0% (w/v) tryptose, 0-3% beef extract and 0-5% NaCl for 18 h at 37°C on a rotary shaker and harvested by continuous-flow centrifugation. Crude cell walls were obtained by vortexing the bacterial pellet with glass beads (0-10-0-15 mm diam.) with buffer (0-01 m-K₂HPO₄/KH₂PO₄, 1-0 m-NaCl, pH 7-4) for 15 min in the 'Bead-Beater' (Biospec Products, Bartlesville, OK, USA). Unbroken organisms and glass beads were removed by filtration through a sintered glass funnel. The crude cell walls were then pelleted by centrifugation at 25000 g for 20 min. After resuspension of the pellet, the crude cell walls were successively treated by suspension in 2% (w/v) sodium dodecyl sulphate with stirring for 16 h; digestion with DNAase, RNAase A, and pronase (Calbiochem) in 0-05 m-Tris/HCl, 0-005 m-MgCl₂, 0-005% thimerosal, pH 7-4; stirring with 40% phenol for 30 min at 25°C; centrifuging and extensive washing with distilled water; and finally lyophilized.

Teichoic acid was removed from the purified cell walls by extraction with 100 ml 10% (w/v) TCA for 72 h at 4°C. The cell walls and debris were removed by centrifugation and the teichoic acid was collected from the supernatant by membrane filtration (Type PM-10, Amicon). This teichoic acid was further treated with lysostaphin, dissolved in 1-0 m-NaCl, 0-005% thimerosal, and applied to a Sephadex G-150 column (Pharmacia) to remove residual cell wall.

Peptidoglycan was prepared from the previously treated cell walls by further extraction of any residual teichoic acid with 20% (w/v) TCA at 60°C for 90 min. The peptidoglycan was then washed four times with distilled water and lyophilized.

Preparation of EXP. The S. aureus Smith diffuse strain was cultured overnight in 41 Columbia broth supplemented with 1% (w/v) yeast extract at 37°C on a rotary shaker. The broth cultures were then formalinized (0-5% fluid concn) and heated to 60°C for 20 min while on the rotary shaker. The pH of the cultures was adjusted to 7-4 and they were shaken overnight with DNAase, RNAase, phosphodiesterase, lysostaphin, and pronase at 37°C. The next morning the pH of the treated cultures was lowered to 2-6 and the unbroken bacteria were removed by centrifugation at 10000 g for 30 min. The supernatant was dialysed against buffer A (pH 2-60), which contained: glycine, 5-1 g l⁻¹; NaCl, 4-0 g l⁻¹; 0-03 m-HCl, and applied to a SP-Sephadex cation-exchange column (type C-50, Pharmacia), then equilibrated with buffer B (pH 2-60), which contained: glycine, 20-3 g l⁻¹; NaCl, 15-8 g l⁻¹; 0-1 m-HCl. The EXP was eluted with buffer C (pH 3-60), which contained: glycine, 70-7 g l⁻¹; NaCl, 58-3 g l⁻¹; 0-06 m-HCl. This eluate was dialysed against 1-0 m-NaCl, 0-02% NaN₃, pH 7-4, and concentrated by membrane filtration (type PM-30).

For molecular-sieve chromatography, the dialysed and concentrated eluate was then applied to a Sepharose 6B column (Pharmacia) and eluted with 1-0 m-NaCl, 0-02% NaN₃, pH 7-4. The immunologically active fractions were dialysed against distilled water, concentrated by membrane filtration, and lyophilized.

Chemical analysis. Antigens for chemical analysis were weighed and hydrolysed, in vacuo, with 3 m-HCl for 16 h at 100°C. Neutral sugars were also analysed after hydrolysis either in 2 M-trifluoroacetic acid at 120°C for 2 h or in 4 m-HCl at 120°C for 3 h. Acid was removed under vacuum during centrifugation at 7000 g. Total protein content was determined by the Lowry method. Amino acids and amino sugars were quantified on an amino acid analyser (Beckman model 120C). Phosphorus was assayed in hydrolysed antigens using the Gemeni inorganic
Staphylococcus aureus exopolysaccharide

phosphorus UV (Electro-nucleonics, Fairfield, NJ, USA). This system was based on the method described by Daly & Ertingshausen (1972) as modified by Amador & Urban (1972). Nucleic acids were quantified by determining the A400 of an aqueous antigen solution and comparing with serial dilutions of yeast nucleic acids (K and K Laboratories, Jamaica, NY, USA).

Pentoses, hexoses, hexosamines and sugar alcohols were determined as their alditol acetate derivatives (Clamp et al., 1971; Fraser & Mallette, 1973). The hydrolysates were dissolved in water (1 ml) and NaBH4 (5 mg) was added. Reduction proceeded overnight and the reaction mixture was made slightly acidic with acetic acid and evaporated in vacuo. Methanolic acetic acid (9:1, v/v) (1 ml) was added and evaporated followed by dry methanol to remove the boric acid. The alditols were acetylated with pyridine and acetic anhydride at 120°C for 20 min. The acetylation mixture was evaporated to dryness and dissolved in acetone. The alditol acetate derivatives were analysed by gas–liquid chromatograph (Perkin-Elmer model 990) fitted with glass columns (0.9 m x 2 mm i.d. and 1.8 m x 2 mm i.d.) of 3% SP-2340 on 100/120 Supelcoport (Supelco). Temperature was programmed from 175 to 225°C at 2°C min⁻¹. Carboxyl groups of uronic acids were reduced by the method of Taylor & Conrad (1972). Acid hydrolysates from the carboxyl-reduced carbohydrates were then analysed as their alditol acetate derivatives (Kozel & Gotschlich, 1982).

Fatty acids were identified as their methyl esters (Metcalf & Schmitz, 1961). Ester-linked fatty acids were first released by saponification with 10% (w/v) potassium hydroxide in methanol and amide-linked fatty acids were released by hydrolysis with 4 M-HCl (Lambert & Moss, 1983). After esterification with boron trifluoride/methanol, the methyl esters were analysed by gas–liquid chromatography using a glass column (1.8 m x 2 mm i.d.) containing 3% SP-2100 DOH on 100/120 Supelcoport.

RESULTS

Determination of isoelectric point

The initial purifications of the EXP from S. aureus strain Smith diffuse involved TCA extraction and also Cetavlon precipitation from culture supernatants as described by McDonald & Karakawa (1970). The precipitates were further purified by treatment with DNAase, RNAase, and trypsin followed by DEAE-chromatography (Pharmacia) with ammonium carbonate elution. A final purification involved application of the precipitate to a Sephadex G-150 column (Pharmacia) and elution with 1·0 M-NaCl, 0·02% NaN₃, pH 7.4.

Since the initial studies of this antigen preparation with crossed immunoelectrophoresis indicated that several components were present (Fig. 1), isoelectric focusing studies were done between pH 7.8 and pH 2.48. Immunologically active components with precipitins to Smith diffuse antiserum were found in three separate bands (Fig. 2). Precipitins were found in fractions from both extremes of the pH range (7.48 and 2.48). Neither of the precipitins from the pH extremes was reactive with Smith diffuse antiserum absorbed with either Smith compact or Smith diffuse micro-organisms (Fig. 2). In contrast, two separate precipitins were localized to a narrow pH band extending from pH 3.52 to 3.96. These precipitins differed in their reactivity to Smith diffuse antiserum absorbed with Smith compact organisms but neither was present against Smith diffuse antiserum absorbed with Smith diffuse organisms (Fig. 2).

Isoelectric focusing between pH 2.00 and 5.82 was also performed on the purified cell wall teichoic acid previously prepared from the Smith compact strain. The teichoic acid was recovered from the most acidic fractions (pH 2.00–2.76).

Immunological analysis of EXP preparation

The method of preparation of the EXP from the S. aureus Smith diffuse strain evolved from the isoelectric focusing findings. Acidified and digested culture supernatant was applied to a cation-exchange column using a dilute pH 2.60 buffer. The column was equilibrated at pH 2.60 and then EXP was eluted with buffer at pH 3.6 (see Methods). Similarly, immunologically active fractions from the Sepharose 6B column were detected in the void volume as determined with Blue Dextran (Pharmacia). The approximate yield of EXP from 4 l culture supernatant was 10 mg.

Crossed immunoelectrophoresis of the final EXP preparation showed two long precipitin lines when Smith diffuse antiserum was employed in the second phase (Fig. 3a). Substitution of Smith diffuse antiserum absorbed with Smith compact organisms in the second phase resulted in almost complete removal of one precipitin line (Fig. 3b). Both precipitin lines were removed
Fig. 1. Crossed immunoelectrophoresis of the initial Smith diffuse EXP preparation (1 mg ml⁻¹). Second-dimension electrophoresis was done into a gel containing rabbit anti-S. aureus Smith diffuse serum.

Fig. 2. Isoelectric focusing of the initial Smith diffuse EXP preparation between pH 7.48 and pH 2.48 revealed antigenic components localized to (A) pH > 7.48, (B) pH 3.6, and (C) pH < 2.48. The immunodiffusion reaction of each component between rabbit anti-Smith diffuse serum (1), anti-Smith diffuse serum absorbed with the variant, Smith compact (2), and anti-Smith diffuse absorbed with Smith diffuse (3) is shown.

when the second phase contained Smith diffuse antiserum absorbed with Smith diffuse organisms. This precipitin pattern was unchanged even when individual fractions throughout the Sepharose 6B peak were analysed separately. Tandem immunoelectrophoresis with Smith diffuse antiserum showed that EXP was not teichoic acid (Fig. 4).

Chemical analysis of staphylococcal antigens

Chemical analysis for amino acids, phosphate, sugar alcohols and amino sugars was done to estimate the contamination of EXP with peptidoglycan or teichoic acid. The results for teichoic acid and peptidoglycan were consistent with published values for these structures (Peterson et al., 1978; Verbrugh et al., 1981). Phosphate was insignificant in the peptidoglycan while it constituted 1.2 μmol (mg teichoic acid)⁻¹ and 0.5 μmol (mg EXP)⁻¹. Muramic acid was not detected in the teichoic acid or EXP. Ribitol was not found in either the peptidoglycan or the EXP. The total protein content calculated from amino acid analysis of the Smith diffuse EXP
Fig. 3. Crossed immunoelectrophoresis of the final Smith diffuse EXP preparation (1 mg ml\(^{-1}\)). Second-dimension electrophoresis was done (a) into a gel containing rabbit anti-Smith diffuse serum, and (b) into a gel containing rabbit anti-Smith diffuse serum absorbed with the variant, Smith compact. In (a), two separate long precipitin arcs are present; the major precipitin is arrowed. In (b), the major precipitin arc (arrow) persists while the second component essentially disappears.

Fig. 4. Tandem immunoelectrophoresis of the Smith diffuse EXP preparation (1 mg ml\(^{-1}\)) (well A) with Smith compact cell wall teichoic acid (0.12 mg ml\(^{-1}\)) (well B). Teichoic acid (arrowhead) was different from the EXP.
was 6.2% or <2% by the Lowry method. Analysis of the EXP for fatty acids failed to reveal that a significant quantity was present. The content of nucleic acids was also insignificant (<1%).

Analysis for neutral sugars after hydrolysis of the EXP at 120 °C for 2 h with 2 M-trifluoroacetic acid revealed primarily glucose and mannose (molar proportion 1:0.90) with trace amounts of galactose and a pentose or deoxy sugar with a retention time similar to xylose (molar proportion 0.12 for each). After more extensive hydrolysis at 100 °C for 3 h with 4 M-HCl, glucose, mannose and galactose were again the principal neutral sugars present (molar proportion 1:0.23:0.13).

After carboxyl reduction of the EXP, the preparation was hydrolysed with 3 M-HCl for 16 h at 100 °C. Analysis of alditol acetate derivatives of this reduced preparation was then compared to the non-reduced EXP. The reduced EXP showed a fivefold increase in glucosamine. This finding suggests that the EXP contained major quantities of 2-amino-2-deoxyglucuronic acid.

**DISCUSSION**

EXP isolated from *S. aureus* strain Smith diffuse essentially as outlined by McDonald & Karakawa (1970) contained significant amounts of teichoic acid. Isoelectric focusing, however, indicated a way to separate the two polysaccharides. The isoelectric point of 3.6 for the exopolysaccharide agreed closely with the value of 3.3 found by Haskell & Hanessian (1963, 1964), whereas teichoic acid was considerably more acid with a value of 2.0. A similar value was reported by Haukenes (1962) and reflects the presence of phosphodiester linkages.

Teichoic acid may be difficult to exclude from staphylococcal EXP preparations (Brock & Reiter, 1976). Liu et al. (1974) reported that EXP was separated from teichoic acid by molecular-sieve chromatography in 1 M-NaCl, which prevented aggregation of the teichoic acid, while Murthy et al. (1983) found that chromatography of the *S. aureus* strain M EXP on QAE-Sephadex A-50 (Pharmacia) was adequate for the removal of teichoic acid. Fournier et al. (1984) reported purification of *S. aureus* type 8 EXP by chromatography on DEAE-Sephacel followed by Sephacryl S-300. Our initial separation of EXP from teichoic acid employed a cation-exchange column at pH 2.60 to ensure binding of the EXP while excluding the teichoic acid. Although Haskell & Hanessian (1963) reported that salt solutions of EXP were not absorbed on sulphonic acid exchange resins, in our hands EXP bound readily with acid buffers, perhaps indicating the presence of basic groups.

Crossed immunoelectrophoresis of the EXP preparation revealed two distinct precipitin lines (Fig. 3), one of which was not removed by absorbing Smith diffuse hyperimmune sera with the nonencapsulated variant, Smith compact. The two components could not be separated by cation-exchange or molecular-sieve chromatography. Ekstedt & Bernhard (1973) reported gel-immunodiffusion studies on EXP prepared from several *S. aureus* strains including Smith diffuse. They found that two precipitin lines formed in the interaction with homologous Smith diffuse antisera. Morse (1962) also noted double precipitin formation of his preparation on gel-immunodiffusion, especially at higher antigen concentrations (1 mg ml⁻¹). He further speculated that this pattern may have been a result of minor structural alterations of the polysaccharide polymers. These studies are difficult to compare because of differences in isolation methods and our use of the more sensitive crossed immunoelectrophoresis. Caputy & Costerton (1984) examined a Smith diffuse EXP preparation with crossed immunoelectrophoresis and reported five separate precipitins.

Ribitol was not detectable in the EXP. The neutral monosaccharides released by hydrolysis were glucose, mannose, and galactose. 2-Amino-2-deoxyglucuronic acid was present, probably N-acylated with acetyl and amino acids. With the exception of neutral monosaccharides, these results are similar to studies by Haskell & Hanessian (1963, 1964) and Hanessian & Haskell (1964). Although total protein content was <2% by the Lowry method, analysis on an amino acid analyser revealed a slightly higher protein content. This estimation may not reflect protein contamination but may include structural components such as amino sugars. Detailed chemical and structural analysis of the Smith diffuse EXP with nuclear magnetic resonance and other nondegradative techniques are in progress.
This method of purification offers an alternative means of separating the Smith diffuse EXP from teichoic acid constituents of staphylococci. Its isolation aids in establishing data regarding its production by clinical strains of \textit{S. aureus} and in furthering serological investigations concerning its immunogenicity in \textit{S. aureus} infections.

We thank Marcia West for her technical assistance. This investigation was supported by Public Health Service grant 1R23AI18654 from the National Institutes of Health.
