Role of Erythrosine in the Inhibition of Adhesion of 
Lactobacillus fermentum Strain 737 to Mouse Stomach Tissue

By PATRICIA L. CONWAY* AND REGINALD F. ADAMS

(Received 23 May 1988; revised 27 September 1988; accepted 26 October 1988)

The mechanism by which the food colour erythrosine inhibits the adhesion of Lactobacillus sp. to squamous epithelium in the mouse stomach was investigated using an in vitro adhesion assay. Inhibition of adhesion occurred only after growth of L. fermentum in erythrosine which bound to the bacterial cell surface. Erythrosine did not interfere with the receptor on the epithelial cell surface. Growth, but not the ATP content per cell, was affected by the presence of erythrosine in the growth medium. No consistent correlation between hydrophobicity and growth in two different broths was noted when erythrosine was present. Analyses of phenol/water extracts and transmission electron micrographs revealed no reduction in extracellular polysaccharide after growth in the presence of erythrosine. It was concluded that erythrosine affects bacterial metabolism thereby preventing production of the bacterial adhesin which is not the extracellular polysaccharide.

INTRODUCTION

Lactobacillus spp. adhere to and colonize the surface of the squamous epithelia of the digestive tract in rodents (Brownlee & Moss, 1961), pigs (Dubos et al., 1965), and chickens (Fuller & Turvey, 1971). This adhesion is host specific (Fuller, 1973; Suegara et al., 1975; Lin & Savage, 1984) and reported to be mediated by a bacterial extracellular polysaccharide (Savage, 1972; Brooker & Fuller, 1975; Barrow et al., 1980). In rodents, however, other surface macromolecules have also been proposed as the adhesins (Suegara et al., 1975; Sherman & Savage, 1986). When the food colour erythrosine was included in the drinking water of rats (Adams & Conway, 1981), a decrease was observed in the number of lactobacilli adhering to the stomach squamous epithelium. The aim of the work presented here was to determine the site of erythrosine inhibition using an in vitro adhesion assay. In addition, the influence of erythrosine on the growth of bacteria and the production of extracellular polysaccharide was also studied.

METHODS

Bacterial strains. Lactobacillus fermentum strain FRR B737 (CSIRO Food Research culture collection, NSW, Australia) was freshly isolated from the keratinized squamous epithelium from the stomach of a healthy adult BalbC mouse by enrichment in Rogosa broth (Oxoid) for 24 h at 37 °C in an anaerobic jar (Oxoid anaerobe gas generating system). The dominant colony type was purified on Rogosa agar (Oxoid) and identified according to Holdeman et al. (1977). The strain was maintained in a freeze-dried state. For each experiment, an overnight primary culture was grown from a fresh ampoule using liquid medium and growth conditions consistent with that used for each experiment. In addition, freeze-dried cultures of the Lactobacillus fermentum strain FRR B735, which was similarly isolated from rat stomach tissue (Adams & Conway, 1981), were used.

Abbreviations: PB, phosphate buffer; BHI, brain heart infusion; MRS broth, de Man, Rogosa and Sharpe Lactobacillus broth; EDAX, energy dispersive analysis X-rays.
Effect of erythrosine on growth. Erythrosine (2,4,5,7-tetraiodofluorescein, disodium salt) was a food-grade commercial preparation (Edicol Erythrosine, ICI Australia) that conformed with the specifications of FD & C Red no. 3 (United States of America Code of Federal Regulations, sec. 962; Federal Register 1970, 35, 1910b). It was used without further purification. The growth of *L. fermentum* strain FRR B737 in Rogosa broth, MRS broth (Oxoid) and Brain Heart Infusion (BHI) broth (Oxoid) was monitored in the presence of 0, 0-05 and 0-1% erythrosine using 1% (v/v) inocula from broth-grown cells. All broths, roll tubes and diluents were prereduced according to Holdeman *et al.* (1977) using resazurin and cysteine. The broths (100 ml) were sampled frequently during incubation at 37 °C for up to 30 h after inoculation. Samples were serially diluted in 10-fold steps in phosphate-buffered saline (PBS; 0-85% NaCl in 0-1 M-potassium phosphate buffer, pH 7-2). Aliquots (0-1 ml) from the serial dilutions were inoculated into roll tubes of MRS agar for enumeration of the colony-forming units (c.f.u.) after 3-5 d incubation at 37 °C.

In addition, the conductivity of the growth medium during growth of *L. fermentum* strain 737 in prereduced BHI broth in the presence of 0-1% erythrosine was monitored over 40 h using a Malthus 8H/L 8-channel conductance system (Imbros Pty). The ATP levels after 24 h growth were measured using a Luminometer model 1070 (Lumac) and ATP (Sigma) as the internal standard.

Hydrophobicity. *L. fermentum* strain 737 was grown in the absence and presence of 0-1% erythrosine in BHI and MRS broths at 37 °C for 24 h in an anaerobic jar using the Oxoid gas generating system. Cultures were centrifuged at 10000 g for 15 min, washed in 10 ml 0-01 M-Tris/HCl buffer, pH 7-0, and resuspended in the same buffer to give a concentration of 10^8 bacteria ml^{-1} as estimated from a standard graph of OD_{664} plotted against number of viable cells (i.e. c.f.u.). The bacterial suspensions from media without erythrosine were divided into two portions and 0-1% erythrosine was added to one fraction immediately prior to the hydrophobicity measurement. Hydrophobicity was tested using 1-2 ml of a washed bacterial suspension and 200 μl xylene according to Rosenberg *et al.* (1980) and is expressed as the mean percentage of cells leaving the aqueous phase, as measured by the reduction in the optical density, in five independent assays using different batches of cells. The measurement was repeated using 0-1 M-potassium phosphate buffer (PB), pH 7-2, instead of 0-01 M-Tris/HCl buffer, pH 7-0. The bacterial suspensions were also tested for adhesion to mouse stomach squamous epithelium (see below).

**In vitro adhesion assay.** BalbC mice (20–25 g) were given free access to a commercial pelletized diet and drinking water supplemented with ampicillin (1 mg ml^{-1}) or 0-25% erythrosine for 4 d and then killed. A minimum of three mice per adhesion study was used. Portions, each approximately 25 mm^2, of the squamous epithelium of the stomach were dissected out and washed three times with 5 ml PBS. In order to avoid centrifuging and washing cells to remove the growth media, because this step could also remove extracellular components, bacteria for the adhesion assay were grown on agar plates. *L. fermentum* strain 737 was incubated for 18 h on Rogosa or BHI agar ± 0-1% erythrosine and harvested from the agar surface in PB (0-1 M, pH 7-2). Bacterial suspensions were adjusted to give approximately 10^8 cells ml^{-1} as enumerated by direct microscopy.

The tissue pieces were added to suspensions of *L. fermentum* strain 737 (three pieces per suspension) and incubated at 20 °C for 30 min with gentle mixing. The tissue pieces were then washed three times in 5 ml PBS and fixed in 3% (w/v) glutaraldehyde in PB for examination by scanning electron microscopy (SEM) for quantification of adhering bacteria according to Adams & Conway (1981). As a control, erythrosine (0-1%) was also included at the time the tissue pieces and bacterial suspensions were mixed. In addition, tissue and bacterial suspensions were incubated with 0-1% erythrosine in PBS at 5 °C for 2 h prior to being used in the *in vitro* adhesion assay. These erythrosine-treated cells and tissue pieces were washed three times in 5 ml PBS to remove unbound erythrosine.

The *in vitro* assay was also done using squamous epithelial tissue aseptically removed from the stomachs of male Wistar rats (4–6-weeks-old) fed the same diet and ampicillin as was supplied to the mice. *L. fermentum* strain 735, isolated from rat stomach (Adams & Conway, 1981), was also used. Strain 735 was incubated at 37 °C in BHI ± 0-05% erythrosine and after 18 h of anaerobic growth, the tissue pieces were added and the incubation continued under anaerobic conditions for an additional 24 h. The tissue pieces were then washed and prepared for SEM. Control tissue pieces were incubated in sterile BHI broth to ensure that residual indigenous flora after the ampicillin treatment did not interfere with the assay.

**Bacterial extracellular polysaccharide.** The extracellular polysaccharides on *L. fermentum* strain 737 grown for 16 h on Rogosa agar ± 0-1% erythrosine at 37 °C were extracted using phenol according to Westphal *et al.* (1952) and assayed according to Dubois *et al.* (1956) using glucose as the standard. The bacterial cells grown in Rogosa and MRS broth for 16 h were also prepared for transmission electron microscopy (TEM) for visualization of extracellular material. Samples were fixed overnight in 3% (w/v) glutaraldehyde in 0-1 M-sodium cacodylate buffer, pH 7-0, postfixed in osmium tetroxide and embedded in Epon. Ruthenium red (0-15%, w/v) was included in fixation and washing solutions. Sections were poststained with 4% (w/v) uranyl acetate and lead citrate (Reynolds, 1963) and examined by TEM.

Because of the required poststaining, material visualized by TEM may not have been ruthenium red stained. To confirm that ruthenium red was detectable at the site of *Lactobacillus*-epithelium interaction, energy dispersive analysis X-rays (EDAX) coupled with SEM were used to confirm the presence of ruthenium on stomach tissue with attached *L. fermentum* strain 737 from the *in vitro* assay. Samples from the *in vitro* assay were prepared for
SEM as described (Adams & Conway, 1981), except that 0·15% ruthenium red was included in the fixing and washing solutions and the samples were vacuum sputter-coated with carbon instead of gold-palladium because of the proximity of palladium and ruthenium in the EDAX detection system.

Location of erythrosine within L. fermentum strain 737. Cells grown in the presence of erythrosine were stained red and the fluorescent character of erythrosine was utilized to determine whether the compound was incorporated within the bacterial cell. An 18 h culture grown in BHI broth containing 0·1% erythrosine was embedded in paraffin at 60 °C and cut to yield sections 6-14 μm thick. The paraffin was removed by melting at 35 °C and the sections rinsed with xylene (10 min) and then stained with cotton blue for 10 min, rinsed with xylene and mounted using the Difco synthetic mounting medium (DPX). The cotton blue solution was prepared the day before use by dissolving 0·05 g cotton blue in 30 ml lactic acid and the solution was filtered before use (0·2 μm pore size). Sections were examined using fluorescent and conventional light microscopy to determine whether erythrosine could be detected inside the cell or only on the cell wall. As a control for the cotton blue stain, an air-dried smear of the erythrosine-grown cells was stained with cotton blue and rinsed with xylene as for the sections.

For preparation of ethanol precipitates of disrupted cells, a 24 h culture grown in BHI broth containing 0·1% erythrosine was centrifuged, washed twice in 10 ml PBS and resuspended in 5 ml PBS. The bacterial cells were disrupted by passing the suspension through a French press three times. The resultant sample was centrifuged at 10000 g for 10 min and the supernatant precipitated with 3 vols ethanol. The precipitate was harvested by centrifugation and then resuspended in a protease solution (2 mg ml⁻¹; Pronase; Calbiochem) in PBS. After incubation at 37 °C for 30 min, the solution was again precipitated with 3 vols ethanol and the precipitate collected by centrifugation. The first and second ethanol precipitates were examined for the presence of erythrosine (red colour) by direct visual observation.

**RESULTS**

**Growth in the presence of erythrosine**

While 0·1% erythrosine was not bactericidal to L. fermentum strain 737, the growth of the bacterium was inhibited when grown in BHI, Rogosa or MRS broth containing either 0·05% or 0·1% erythrosine. Data for growth in BHI broth ± 0·1% erythrosine are presented in Fig. 1(a). The change in conductivity of the medium during growth in BHI broth was studied and a marked difference was detectable when erythrosine was included (Fig. 1(b)). Cells grown for 24 h in prereduced BHI broth in the absence or presence of 0·1% erythrosine contained 2·2 ± 0·3 pg ATP per cell and 4·1 ± 0·4 pg ATP per cell, respectively, each value being the mean ± SD of four individual assays.

**Hydrophobicity measurements**

Bacterial cells grown in the presence of erythrosine were red in colour and remained so even after removal from the growth medium and subsequent washings in buffer. The hydrophobicity decreased significantly (P < 0·05) when the bacteria were grown in MRS broth containing 0·1% erythrosine but not when grown in BHI broth containing 0·1% erythrosine (Table 1). The inclusion of 0·1% erythrosine in the bacterial suspension immediately prior to the hydrophobicity measurement had no effect on BHI-broth-grown cells but did increase significantly (P < 0·01) the hydrophobicity of the MRS grown cells. Growth in both MRS and BHI broth containing erythrosine prevented adhesion, and comparable values to those presented in Table 1 were obtained when PB was used instead of Tris buffer (data not presented).

**In vitro adhesion**

The adhesion of L. fermentum strain 737 to mouse stomach epithelium when bacteria and/or tissue pieces were independently exposed to 0·1% erythrosine is presented in Table 2. While a slight reduction in adhesion can be noted after short-term exposure of either tissue or bacterial cells to erythrosine, as well as when using tissue from an erythrosine-fed animal, significant inhibition of adhesion (P < 0·01) was demonstrated only when the bacterial cells were grown in the presence of the erythrosine.

A similar inhibitory effect was observed using the rat-derived L. fermentum strain 735 and rat stomach epithelium. The surface of the control pieces of tissue incubated in sterile BHI broth remained intact and devoid of bacteria after the 24 h incubation period. The number of bacteria
Fig. 1. Anaerobic growth of *L. fermentum* strain 737 at 37 °C in BHI broth in the absence (○) or presence (●) of 0-1% erythrosine. Viable counts (a), expressed as log<sub>10</sub> (no. of c.f.u. ml<sup>-1</sup>) and conductivity (b), expressed as the change in impedance of the growth medium, are plotted against time of incubation. Results are typical of four individual experiments.

Results are typical of five individual experiments. Statistical probability was assessed using Student’s t-test: *P < 0·01 compared to MRS–737 value; eP < 0·05 compared to MRS–737 value; cP < 0·01 compared to BHI + Ery value; dP < 0·01 compared to MRS + Ery value.

per 100 μm<sup>2</sup> of tissue surface, as enumerated by SEM, was 18·6 ± 7·0 (mean ± SD) when incubated with the bacteria in BHI broth and zero when 0·05% erythrosine was included in the BHI broth. As strain 735 grew poorly in 0·1% erythrosine, adhesion was tested for cells grown in 0·05% erythrosine.

*Bacterial extracellular polysaccharide*

The phenol/water extracts of the bacteria grown on Rogosa agar contained 20·9 and 22·7 μg glucose per mg dry wt of cells grown in the absence or presence of 0·1% erythrosine, respectively. There was no correlation between amounts of extractable saccharide and adhesion because

those grown on Rogosa agar adhered to stomach tissue while those grown on Rogosa agar + 0·1% erythrosine did not adhere. TEM confirmed that the growth of the bacteria in Rogosa broth containing 0·1% erythrosine had no detectable effect on the extracellular material because layers of 0·036 and 0·038 µm thickness were noted around control and erythrosine-grown cells, respectively. The EDAX system confirmed that the acid-polysaccharide stain, ruthenium red, reacted with the bacterial cell because the peak representing elemental ruthenium was detected by EDAX only on stomach tissue with adhering bacteria as visualized by SEM. The stained material visualized by TEM could not be confirmed to contain ruthenium red, hence the use of the EDAX system.

**Location of erythrosine within *L. fermentum***

Cotton-blue-stained sections of cells of *L. fermentum* strain 737 grown in the presence of erythrosine were examined using conventional and fluorescent light microscopy. Those bacterial cell sections containing erythrosine, as visualized by UV light, were not stained with cotton blue and conversely those bacterial sections which retained the cotton blue stain were not fluorescent. Exposure to cotton blue of air-dried smears of *L. fermentum* strain 737, after growth in the presence of erythrosine, did not result in staining of intact whole cells or cell walls. Thus any material in a section that was stained with cotton blue must have been cytoplasmic. As no material that stained with cotton blue contained erythrosine, it seems that the internal cell constituents were not stained with erythrosine.

The initial ethanol precipitate of the disrupted cells contained erythrosine. After incubation with protease, no erythrosine was detected in the ethanol precipitates, indicating that erythrosine was located in association with protein components of cell-wall fragments.

**DISCUSSION**

The red food colour erythrosine was not bactericidal to *L. fermentum* strain 737 when grown in the two laboratory broths in this study (Fig. 1a). This is consistent with the suggestion from earlier *in vivo* studies that the *Lactobacillus* in the rat digestive tract remained viable in the presence of erythrosine (Adams & Conway, 1981). Although *L. fermentum* remained viable, bacterial growth (Fig. 1a) and the conductance of the growth medium (Fig. 1b) were reduced by erythrosine and as the concentration of erythrosine was increased, so too was the effect on
bacterial growth. The change in conductance of the medium during growth reflects the metabolism of the bacterial cell because it measures the change in electrical conductivity of the solution as bacterial metabolites are released into solution. The detected reduction of the change in impedance of the culture fluid (Fig. 1b) for bacterial growth in the presence of erythrosine suggests an alteration in the metabolism of those cells grown in medium containing erythrosine. This inhibitory effect of erythrosine on metabolism did not affect the amount of ATP per cell, a measurement suggested to reflect metabolic activity of aerobic micro-organisms (Gustafsson, 1979). As L. fermentum is heterofermentative and the ATP yield for heterofermentative bacteria is only 1 mol per mol of glucose, changes in metabolic activity may only induce small changes in ATP yield for this organism, and ATP measurements as made here may be too insensitive. Although unsupported by the ATP values, the reduction of growth and conductance of the growth medium support the fact that erythrosine altered the metabolism of the bacterial cells.

No consistent correlation existed between growth in erythrosine and altered hydrophobicity and adhesion for cells grown in BHI or MRS broths. While the short-term exposure of BHI-broth-grown cells to erythrosine did not alter hydrophobicity (Table 1), the observed increase for similarly treated MRS-broth-grown cells may occur because of erythrosine binding to surface components which were located only on the cell surface after growth in MRS broth. An explanation for the observed decreased adhesion for bacteria grown in MRS broth plus erythrosine may be that hydrophobic components on the bacterial cell surface become more easily released from the bacterial surface during the two-phase separation. This could not be confirmed by the commonly used alternative hydrophobicity measurement, hydrophobic interaction chromatography, because the cells were so hydrophobic that they did not pass through a column (data not presented). It is therefore difficult to evaluate the role of hydrophobicity in the adhesion of the L. fermentum strain 737 to the tissue from the results presented.

The in vitro adhesion studies clearly demonstrate that erythrosine plays an active role in preventing or reducing expression of the adhesive capacity of L. fermentum strain 737 to mouse stomach tissue rather than interfering with the receptor on the epithelial surface. This was confirmed for both the mouse and rat system and would explain why the Lactobacillus population was lost from the stomach surface in vivo when animals were given erythrosine in their drinking water for 4 d (Adams & Conway, 1981). It is interesting to note that the adhesion of agar-grown cells (Table 2) is greater than that of broth-grown cells (Table 1). This supports the original rationale for using agar-grown cells as growth and/or harvesting from the broth phase appears to reduce the adhesive capacity. This phenomenon has previously been reported for the adhesion of E. coli to mouse small-intestinal epithelium (Zilberberg et al., 1984).

The concentration of ruthenium red (determined by EDAX) on the tissue surface where the Lactobacillus cells were located, and the extracellular material detectable by electron microscopy, is consistent with the findings of others (Brooker & Fuller, 1975; Barrow et al., 1980) that an extracellular acidic polysaccharide is detectable by microscopy on adhering bacteria. However, a correlation between adhesive capacity and quantitative expression of the ruthenium-stained material was not substantiated by the phenol/water extract analyses for saccharides or by TEM of erythrosine-grown cells. Even though the saccharide analysis of Dubois et al. (1956) may not detect some saccharides, the methodology used for TEM was consistent with that used by Brooker & Fuller (1975). While the polysaccharide may play an active role in adhesion, from the data presented here it seems that it is not used for the initial phase of attachment, as detected by the in vitro adhesion assay. This fact is supported by other studies: (i) L. fermentum strain 737 devoid of extracellular polysaccharide maintained adhesive characteristics (P. L. Conway, L. Rüdén, T. Nyström and S. Kjelleberg, unpublished results); (ii) Suegara et al. (1975) found no clear correlation between the extracellular polysaccharide and adhesion to rodent stomach tissue; (iii) Savage (1984) suggested that Lactobacillus adhesion to mouse stomach tissue possibly involves several extracellular compounds and Sherman & Savage (1986) suggested that lipoteichoic acid may be involved.

The role of erythrosine in inhibiting adhesion could not be elucidated from studies of the extracellular polysaccharide or the hydrophobicity of the cell surface. Because erythrosine was
localized on cell-surface proteins, it may alter the bacterial cell surface and possibly thereby alter the transport of nutrients and metabolites in and out of the cell.

In summary, it is concluded that erythrosine altered the metabolism of *L. fermentum* strain 737 and thereby prevented the expression or transport of the material responsible for initiating adhesion of the bacterial cells to the stomach tissue surface *in vitro*. It seems that adhesion was not mediated by either hydrophobic interaction or by the extracellular polysaccharide but rather by another bacterial metabolite. Additional studies suggest that an extracellular protein plays a significant role in adhesion [Conway, 1986; Conway & Kjelleberg, 1989 (accompanying paper)].

This work was largely performed at the CSIRO Division of Food Research Laboratory, North Ryde, Australia, and some aspects were supported by Chemical Dynamics, Sweden. Lena Töyrä, University of Göteborg, is thanked for her assistance with the transmission electron micrographs.
