**Introduction**

Tyrosinase (EC 1.14.18.1) catalyses the oxidation of L-tyrosine via L-dihydroxyphenylalanine (L-Dopa) to dopaquinone, which oxidizes spontaneously and polymerizes to form melanin. Many *Streptomyces* species have a tyrosinase gene but the functions of tyrosinase and melanin are unknown. In *Streptomyces glaucescens* the tyrosinase contains two copper atoms per molecule. Both copper atoms are bound to two histidine residues in the active centre of the enzyme and both are necessary for the activity of the enzyme (Huber & Lerch, 1988). In *S. glaucescens*, tyrosinase activity can be induced by various amino acids, including L-methionine, L-leucine and L-phenylalanine, but not L-tyrosine (Baumann & Kocher, 1976; Kieser et al., 1976), while the tyrosinase of *Streptomyces antibioticus* is induced at low effector concentrations only by L-methionine (Katz & Betancourt, 1988).

According to Crameri et al. (1982) the tyrosinase of *S. glaucescens* first occurs cell-bound and is then released into the medium, where the formation of melanin takes place. The intracellular and extracellular forms of the enzyme are identical and consist of a single polypeptide chain of approximately 31 kDa (Lerch & Ettlinger, 1972; Huber et al., 1985). Surprisingly, no signal peptide sequence could be found in the tyrosinase structural gene. The DNA sequences coding for the tyrosinasises of *S. glaucescens* (Huber et al., 1985) and *S. antibioticus* (Bernan et al., 1985) show 85.8% homology and the two protein sequences are 86.4% identical. Both the *S. glaucescens* and the *S. antibioticus* tyrosinase structural genes are preceded by very similar small open reading frames specifying proteins with amino-terminal signal peptides characteristic of exported proteins. Lee et al. (1988) showed that the upstream open reading frame (ORF<sub>138</sub>) of *S. antibioticus* specifies a trans-acting factor which seems to facilitate the incorporation of copper into the apotyrosinase.

In *S. antibioticus* (Katz & Betancourt, 1988) and *S. michiganensis* (Platen & Kutzner, 1986) the amount of active tyrosinase formed correlated with the concentration of copper added to the medium. In this paper we present evidence that the biosynthesis of the tyrosinase of *S. michiganensis* is induced by copper and repressed by ammonium.

**Methods**

*Micro-organisms and cultivation.* *S. michiganensis* DSM 40015 and its mutant derivatives were grown in a synthetic medium (SM) at 28 °C. SM contained, in g l<sup>-1</sup>: glucose, 10.0; arginine·HCl, 5.0; MgSO<sub>4</sub>·7H<sub>2</sub>O, 0.2; FeCl<sub>3</sub>·6H<sub>2</sub>O, 0.05; KH<sub>2</sub>P<sub>2</sub>O<sub>4</sub>, 1.0; K<sub>2</sub>HPO<sub>4</sub>, 1.0; trace element solution (without copper), 1·0 ml (Drews, 1983); pH 7.2. Copper (CuSO<sub>4</sub>) was added at various times to a final concentration of 10<sup>-4</sup> M. Solid media contained 12 g agar l<sup>-1</sup>. Tyrosine (1·0 g l<sup>-1</sup>) was added for the detection of melanin formation. The complex medium (CM) used contained, in g l<sup>-1</sup>: glucose, 10.0; peptone, 5.0; meat extract, 5.0; yeast extract, 5.0; pH 7.2.

Cultures were grown in 1 litre Erlenmeyer flasks containing 400 ml medium on a rotary shaker (170 r.p.m.). At appropriate time intervals samples were removed from the cultures to assay enzyme activities.

For radioactive labelling of proteins, [35S]methionine (specific...
activity 1000 Ci mmol⁻¹; 37 TBq mmol⁻¹) was added at the time of Cu²⁺ induction, to give 1-25 μCi per ml medium.

Reproducibility of results. The experiments were repeated twice and the mean results are shown.

Detection of actinomycin production. Plugs (6 mm diameter) were cut from 5-d-old SM agar cultures, transferred onto an agar plate (CM) confluent with inoculated with Bacillus subtilis DSM 347, and incubated for 3 h at 4°C and then overnight at 37°C.

Preparation of crude cell extracts and culture filtrates. Cultures were harvested by centrifugation at 12000 g for 5 min at 4°C and the supernatant was used as culture filtrate for enzyme assays. The cells were washed once with 100 mM-sodium phosphate buffer, pH 6.8, 5 mM-EDTA and disrupted in the same buffer by sonication for 3 min (50% intervals), 50 W, at 0°C using a Branson sonifier model 125. Cell debris was removed by centrifugation at 30000 g for 30 min at 4°C. The resulting supernatant was used as crude extract for enzyme assays. Protein concentrations in crude extracts and culture filtrates were determined by the method of Bradford (1976).

Determination of enzyme activities. Tyrosinase activity was measured polarographically with a YSI Biological Oxygen Monitor model 5300 (Jerumakis et al., 1976). The reaction was carried out in 2.5 ml 0.1 mM-sodium phosphate buffer, pH 6.8, 5 mM-EDTA, with 1 mM-3,4-dihydroxy-L-phenylalanine as substrate. One unit of tyrosinase activity is defined as the amount of enzyme causing the consumption of 1 nmol O₂ s⁻¹.

Polyacrylamide gel electrophoresis. This was done according to Blackshear (1984), in 0.7 M-β-alanine buffer (adjusted with glacial acetic acid to pH4.5) at 4°C. Bromophenol blue was used as the tracking dye. After electrophoresis, gels were stained for tyrosinase activity polarographically with a YSI Biological Oxygen Monitor model 5300 or tyrosinase activity at the beginning of the exponential phase, which was presumably due to small amounts of tyrosinase activity at the beginning of the exponential phase, which was presumably due to small amounts of copper contaminating the components of the medium (Platen & Kutzner, 1986). While the addition of 10⁻⁷ M-CuSO₄ did not result in increased tyrosinase activity, higher concentrations (5 x 10⁻⁶ M and 10⁻⁵ M) led to a dramatic increase of enzyme activity. Growth was slightly impaired by 10⁻⁴ M-CuSO₄, but not significantly influenced by the other copper concentrations used.

Results

Influence of various copper concentrations on activity of tyrosinase in the medium

As shown in Fig. 2, a positive correlation between addition of copper to the medium and the activity of tyrosinase could be demonstrated. The control culture with no copper added showed only a very small peak of tyrosinase activity at the beginning of the exponential phase, which was presumably due to small amounts of copper contaminating the components of the medium (Platen & Kutzner, 1986). While the addition of 10⁻⁷ M-CuSO₄ did not result in increased tyrosinase activity, higher concentrations (5 x 10⁻⁶ M and 10⁻⁵ M) led to a dramatic increase of enzyme activity. Growth was slightly impaired by 10⁻⁴ M-CuSO₄, but not significantly influenced by the other copper concentrations used.

**Addition of copper at various growth phases**

The kinetics of tyrosinase formation and of growth as influenced by the addition of copper at three different times during the early and late growth phase is shown in Fig. 3. Without addition of copper, low tyrosinase activity (as shown in Fig. 2) was formed. The addition of copper at 20, 30 or 47 h after inoculation resulted in an increase in both cell-bound and extracellular tyrosinase activity within about 1 h. In the case of copper addition in the late growth phase (47 h), a short time after copper supplementation the cells began to produce active cell-bound enzyme, which was later released into the medium. The production rate was apparently higher than the excretion rate, resulting in cell-bound tyrosinase showing a peak about 5 h after copper addition.

The following experiments proved that the effects seen in Figs 2 and 3 were due to an induction of the tyrosinase by copper and not simply due to incorporation of copper in a preformed apotyrosinase.

**Absence of in vitro activation of an apotyrosinase by copper**

Crude cell extracts and culture filtrates were prepared from cultures without added copper, at times corresponding to the highest cell-bound (52 h) and extracellular (90 h) tyrosinase activities of copper-induced cultures. The crude extracts and culture filtrates were supplemented with CuSO$_4$ ($10^{-4}$ M, final conc) and incubated for 0, 30, 60, 90, 120 and 180 min at 28°C. The addition of Cu$^{2+}$ to these samples did not result in the formation of any enzyme activity.

**Inhibition of enzyme induction by chloramphenicol**

When chloramphenicol was added to a 47-h-old culture at the same time as Cu$^{2+}$ no tyrosinase could be detected, whereas the control culture (without chloramphenicol) showed the expected production of tyrosinase (Fig. 4). Addition of chloramphenicol 3.5 h after the addition of
Cu$^{2+}$ stopped further enzyme production and resulted in a slow decrease of cell-bound enzyme activity. These effects suggest that copper induces de novo synthesis of tyrosinase.

$[^{35}S]$Methionine labelling of proteins at the time of copper induction

$[^{35}S]$Methionine was used for labelling for two reasons: (i) methionine does not induce the tyrosinase of S. michiganensis, in contrast to the enzyme of S. glaucescens (Baumann & Kocher, 1976) and S. antibioticus (Katz & Betancourt, 1988); (ii) the tyrosinases of the latter two species contain five methionine residues per molecule (Huber et al., 1985; Bernan et al., 1985). Since the tyrosinase of S. michiganensis is a basic protein with a PI of 9.0 (data not shown), the crude extracts from copper-induced and non-induced cultures were electrophoresed in an acidic gel (pH 4.5). The tyrosinase band was localized by activity staining (Fig. 5 b, c). The autoradiography of this gel exhibited a signal for tyrosinase in the copper-induced samples (Fig. 5 e) but not in the controls (Fig. 5 d).

Repression of tyrosinase formation by ammonium

Experiments with various media revealed that on minimal medium containing NH$_4$Cl (1 g l$^{-1}$) as nitrogen source no formation of melanin or of the antibiotic actinomycin occurred. On the other hand, the amino acids arginine, glutamine, aspartic acid and asparagine (5 g l$^{-1}$ each), and also KNO$_3$ and urea (1 g l$^{-1}$ each), allowed the formation of both melanin and actinomycin. These results suggest that both tyrosinase and actinomycin production are repressed by ammonium.

Reversal of ammonium repression

Three cultures grown with NH$_4$Cl as nitrogen source were treated as shown in Fig. 6. While the addition of

(a) Standard proteins (A, aldolase, 149.0 kDa, pl 8.4; C, chymotrypsinogen, 25.5 kDa, pl 9.2; M, myoglobin, 17.8 kDa, pl 7.0; L, lysozyme, 13.9 kDa, pl 11.0; Cy, cytochrome c, 12.8 kDa, pl 9.8). (b, c) Activity stain of tyrosinase; (d, e) autoradiography of labelled proteins. (b, d) Samples of protein from cells non-induced by copper; (c, e) Samples of protein from copper-induced cells. Cells were grown in SM + arginine. After 46 h $[^{35}S]$methionine and Cu$^{2+}$ were added. At 0 h (lane 1), 1.2 h (lane 2), 2.7 h (lane 3), 4.7 h (lane 4), 6.2 h (lane 5) and 7.7 h (lane 6) the cells were sampled, disrupted and the proteins (20 µg per slot) were electrophoretically separated on a native acidic polyacrylamide gel (12.5%, w/v). After activity staining with 3,4-dihydroxy-L-phenylalanine to locate the tyrosinase band, the gel was exposed to an autoradiography film for 10 d.](image)
Tyrosinase induction in *S. michiganensis*

1. Removal of ammonium repression. Three cultures were grown in the synthetic medium containing 18 mM-\(\text{NH}_4\text{Cl}\) (1 g l\(^{-1}\)) as nitrogen source. After 54 h (arrows) the flasks were treated as follows: ○, addition of \(\text{CuSO}_4\) (10\(^{-4}\) M final concn); ○, addition of \(\text{CuSO}_4\) (10\(^{-4}\) M) and arginine (5 g l\(^{-1}\) final concn); Δ, the culture was harvested by centrifugation and transferred into synthetic medium containing arginine (5 g l\(^{-1}\)) and \(\text{CuSO}_4\) (10\(^{-4}\) M).

Copper alone had no effect, when both copper and arginine were added an increase of tyrosinase formation and a second growth phase occurred after a long lag phase of about 40 h. However, harvesting and transfer of ammonium-grown mycelium into synthetic medium containing arginine and copper caused a dramatic increase in both tyrosinase formation and growth within only 5 h.

The repression of tyrosinase biosynthesis depended on the concentration of ammonium in the medium (Fig. 7): with 4 mM-\(\text{NH}_4^+\) only about two-thirds of the control activity (0 mM-\(\text{NH}_4^+\)) was obtained. 10 mM-\(\text{NH}_4^+\) repressed tyrosinase formation almost completely.

**DNA dot-blot hybridization**

DNA dot-blot hybridization of pTH-cif and pTH-tyr with different dilutions of total DNA (1-6 \(\mu g\) to 0-04 \(\mu g\)) isolated from *S. michiganensis*, *S. antibioticus* and *S. lividans* was carried out at a stringency of 73% (data not shown). Both probes gave signals with the DNA from the melanin-producing *S. antibioticus* (positive control), and the DNA from *S. michiganensis*. No signal could be obtained with the DNA of *S. lividans* (negative control, melanin-negative). The specificity of the probes was proved by demonstrating that the SalI fragment of the tyrosinase structural gene cloned into pTH-tyr did not hybridize with the sequence of ORF\(_{438}\) at the level of 73% homology (not shown). Based on this result it is evident that *S. michiganensis* possesses a gene related to ORF\(_{438}\).

**RNA dot-blot hybridization**

After proving the specific hybridization of pTH-mel with total DNA isolated from *S. michiganensis*, this probe was used for dot-blot experiments (Fig. 8). While
hybridization with RNA isolated from copper-induced, ammonium-non-repressed cells gave a strong signal (a), only a weak signal could be obtained with RNA from copper-non-induced, ammonium-non-repressed cells (b). No signal could be found using RNA from copper-induced, ammonium-repressed cells (c). These results show that both copper induction and ammonium repression of tyrosinase production occur at the level of transcription, and that ammonium-repressed tyrosinase biosynthesis cannot be induced by copper.

Discussion

Since tyrosinase contains copper in its active site, the necessity of this metal for the formation of the active enzyme is obvious. Lee et al. (1988) were able to partially re activate apotyrosinase, prepared by KCN treatment, by adding low concentrations of copper. In our experiments no increase in tyrosinase activity occurred upon addition of copper to crude extracts and culture filtrates of S. michiganensis grown without copper. This indicated that no apotyrosinase was present in copper-free cultures of S. michiganensis a result confirmed by $^{35}$S-labelling (Fig. 5).

Hybridization experiments revealed that a gene related to the S. antibioticus ORF$_{438}$ (whose gene product is probably responsible for the incorporation of copper into apotyrosinase; Lee et al., 1988) might be present in S. michiganensis. In addition, genetical and protein chemical data (unpublished) of the tyrosinase of this species are in agreement with corresponding data for the tyrosinase of S. glaucescens; it therefore appears that the genetics and biosynthesis of tyrosinase are similar in S. glaucescens, S. antibioticus and S. michiganensis although the tyrosinase of S. michiganensis is not inducible by L-methionine. Assuming for S. michiganensis the same gene arrangement as in S. glaucescens and S. antibioticus, i.e. the formation of a polycistronic mRNA containing ORF$_{402}$ or ORF$_{438}$ respectively and the structural gene of the tyrosinase, it seems reasonable that in S. michiganensis copper induces the tyrosinase structural gene as well as the copper-incorporation factor and possibly in addition a regulatory cell-bound copper-binding protein.

Nitrogen regulation is a common phenomenon among bacteria (Kleen, 1984). In Streptomyces the formation of a large number of antibiotics is regulated by ammonium (Klein kauf et al., 1986). In this study it was shown that ammonium repressed the formation of tyrosinase and actinomycin in S. michiganensis. The addition of arginine to liquid cultures of S. michiganensis grown with $\text{NH}_4\text{Cl}$ is followed by tyrosinase biosynthesis as well as by increased growth although only after a long lag phase. This suggests that the metabolism of arginine is also re pressed as long as $\text{NH}_4\text{Cl}$ is present in the medium: metabolism of arginine and tyrosinase biosynthesis started only after the ammonium in the medium was exhausted. Furthermore it was shown by several experiments in this study (Figs 6, 7 and 8) that ammonium-repressed tyrosinase formation could not be induced by addition of copper; therefore the ammonium repression might be an overriding mechanism of enzyme regulation. We isolated three ammonium-derepressed mutants (amd; MIC150, MIC153, MIC154) by plating NTG-mutagenized spores on synthetic medium containing tyrosine (1 g l$^{-1}$), CuSO$_4$ (10$^{-4}$ M) and $\text{NH}_4\text{Cl}$ (1 g l$^{-1}$) as nitrogen source. Since none of the mutants were very stable, only preliminary tests could be carried out. Agar plate tests showed that tyrosinase and actinomycin were formed by mutants MIC150 and MIC153 on medium containing ammonium as sole nitrogen source. MIC154 synthesized only tyrosinase on this medium. Mutants MIC150 and MIC154 did not form aerial mycelium. Since the ammonium repression of the formation of both tyrosinase and actinomycin occurred at the level of transcription, as shown by hybridization experiments, and since both effects could be abolished in mutants MIC150 and MIC153, a pleiotropic intracellular effector mediating nitrogen control via nitrogen-regulated promoters might be responsible for this effect. According to this model, MIC154, which is derepressed only in tyrosinase formation, might be a promoter mutant.
