---

**Introduction**

Bacteria of the genus *Azospirillum* are known to colonize the rhizosphere of plants and to promote plant growth under certain conditions. They show only moderate host specificity in colonization, as is reflected by their isolation from a wide variety of plants all over the world. The capacity of azospirilla to colonize the rhizosphere, although not fully understood, is presumed to depend on several bacterial properties, like chemotaxis towards root exudates, a versatile metabolism including nitrogen fixation, antagonism towards competing microorganisms, cyst formation allowing survival under adverse conditions, and, most importantly, the ability to bind to plant roots and soil particles (see reviews by Elmerich, 1984; Okon, 1985; Döbereiner & Pedrosa, 1987; Michiels et al., 1989).

The mechanism of attachment to plant tissue has been well described in a number of other bacteria that interact with plants. For instance, in *Klebsiella pneumoniae* (Korhonen et al., 1983), *Pseudomonas fluorescens* (Vesper, 1987) and *Bradyrhizobium japonicum* (Vesper & Bauer, 1986), attachment to grass, corn and soybean roots, respectively, could be attributed to the presence of bacterial pili. A different *P. fluorescens* strain adsorbed to sand by means of a 34 kDa major outer-membrane protein, identified as flagellin (Deflaun et al., 1990). Attachment of the symbiotic *Rhizobium* bacteria to their specific legume host plant is thought, at least in some cases, to be mediated by a root lectin that recognizes a specific receptor on the bacterial cell surface. Evidence for this lectin hypothesis was recently presented by Diaz et al. (1989), who made white clover susceptible to nodulation by *Rhizobium leguminosarum* bv. *viciae*, which normally nodulates pea, by expressing the pea lectin gene in white clover. Several bacterial cell-surface components have been implicated in the binding of the crown gall pathogen *Agrobacterium tumefaciens* to plant tissue: lipopolysaccharide, which in purified form inhibits binding of *A. tumefaciens* cells to wounded bean leaves (Whatley et al., 1976); β-1,2-glucan, which is absent or not correctly transported to the periplasmic space in a number of non-attaching mutants (Puvanesarajah et al., 1985; Cangelosi et al., 1987, 1989); two outer-membrane proteins not related to flagella or pili (Matthysse, 1987); and cellulose fibrils, which are synthesized by *A. tumefaciens* after the initial adsorption, and which anchor the bacteria to the plant tissue (Matthysse et al., 1981; Matthysse, 1983).
Several studies have described attachment of *Azospirillum brasilense* to both plant roots and inert surfaces, but the mechanisms remain the subject of conflicting hypotheses. *A. brasilense* was shown to bind to grass (Umali-Garcia et al., 1980), maize (Gafny et al., 1986), wheat (Jain & Patrquin, 1984) and rice roots (Murty & Ladha, 1987), and to suspended *Zinnia* cells (Eyers et al., 1988). *Azospirillum* cells often bound in higher numbers than other rhizosphere bacteria (Umali-Garcia et al., 1987), and to suspended root exudate. Involvement of a root lectin was also suggested by Del Gallo et al. (1980), who showed that binding of wheat germ agglutinin by *A. brasilense* and *Azospirillum lipoferum* cells. Madi & Henis (1989), in contrast, isolated an *A. brasilense* cell-surface agglutinin that was necessary for adsorption of the bacteria to wheat roots. Bashan & Levanony (1989) reported that binding of *A. brasilense* to sand and to wheat roots could be eliminated by protease treatment of the bacteria, which supports the involvement of bacterial surface protein. They also studied the effect of cellulase on adsorption of *A. brasilense* to wheat roots. Treatment of the bacteria decreased adsorption moderately, whereas treatment of the wheat roots caused a significant increase in adsorption (Bashan & Levanony, 1989).

In the present paper, two classes of *A. brasilense* attachment mutants are distinguished using two different *in vitro* binding assays to wheat roots. This provides a genetic basis to postulate the involvement of adsorption and anchoring phenomena during attachment of *A. brasilense* to wheat roots.

### Methods

**Bacterial strains and culture conditions.** The bacterial strains used are listed in Table 1. *Escherichia coli* and *Azospirillum brasilense* were grown at 37°C and 30°C, respectively. All strains were kept and restreaked every three weeks on fresh plates of Luria-Bertani (LB) medium (Sambrook et al., 1989) supplemented with 2.5 mM-CaCl₂ and 2.5 mM-MgSO₄. For adsorption and anchoring experiments, a single colony from a fresh stock plate was inoculated in 5 ml supplemented LB in a test tube and 20 μCi of [1',2',5'-3H]CTP (57 Ci mmol⁻¹, 2-11 TBq mmol⁻¹; Amersham) was added. Cultures were grown aerobically in a rotary shaker to an optical density (OD₆₀₀) of 1.0, corresponding to 3 × 10⁸ bacteria ml⁻¹, as determined by plating. When appropriate, 25 μg kanamycin sulphate ml⁻¹ was added to the plates or to the liquid cultures.

**Cultivation of wheat seedlings and preparation of roots.** Seeds of *Triticum aestivum* cv. Fidel (SES, Belgium) were surface-sterilized by immersion in 70% (v/v) ethanol for 3 min, washing three times in sterile distilled water, soaking three times for 30 min in a solution of sixfold diluted commercial bleach containing 0.5% sodium dodecyl sulphate, rinsing with sterile water for 60 min, soaking in fresh bleach/sodium dodecyl sulphate solution of the same composition for 60 min, and finally rinsing five times with sterile distilled water. Sterilized seeds were germinated on Nutrient Agar plates (Difco) for 3 d at 23°C in the dark. Sterile seedlings were individually and aseptically transferred to cotton-plugged 200 × 22 mm glass tubes containing 30 g sterilized sand (0.4-0.8 mm). Per tube, 4 ml of MPCL nutrient solution (Lavigne, 1987) was added, and tubes were placed in a growth chamber with a 16 h day/8 h night cycle, a constant temperature of 23°C, and a relative humidity of 80%. From 2-3-week-old seedlings with approximately equally-sized root systems, roots were cut, washed free of sand with sterile distilled water, and placed individually in sterile test tubes containing 4.5 ml MPCL medium.

**Bacterial adsorption to wheat roots.** Radioactively labelled bacteria grown as described above were collected by centrifugation, washed twice in sterile 0.85% NaCl to remove unincorporated label, and resuspended to the original volume in MPCL medium. The specific activity obtained in this way was in the range of 10⁻²-10⁻³ c.p.m. per bacterium. Portions (0.5 ml) of labelled and washed bacterial cells were

* Cal refers to colony fluorescence on plates containing 200 μg Calcofluor ml⁻¹: Cal⁺, wild-type fluorescence; Cal⁻, no fluorescence; Cal⁴, dimmed fluorescence. Sm', streptomycin resistant; Km', kanamycin resistant.
added to six test tubes containing a wheat root in 4.5 ml MPCL. After 2 h incubation in a rotary shaker at 30 °C, the bacterial suspensions were decanted, and the roots were washed three times by immersion in distilled water for 1 min without agitation. The amount of radioactivity associated with the root was measured in a liquid scintillation counter, and for each root the percentage of the total added radioactivity (in distilled water for 1 min without agitation. The amount of radioactivity in NMF is a nitrogen-free minimal salts medium containing 0.5% fructose, and induces high exopolysaccharide production (Michiels et al., 1990). With the present assay, we wanted to test whether this polysaccharide would promote binding of A. brasilense to wheat roots. The anchoring kinetics in Fig. 1(b) suggest that this is indeed the case. Two binding phases can be clearly distinguished: a rapid adsorption in the first 2 h of incubation, and an additional binding phase initiating after 8 h of incubation and reaching a constant level of 11.1% of the initial inoculum after 16 h, corresponding to 1.7 × 10^7 bacteria per root. Binding of E. coli HB101, by comparison, is not biphasic and is about 70 times lower after 16 h of incubation. Bacteria anchored to wheat roots in this assay could not be released by vortexing in water or in 2.5 mM-EDTA (Table 2).

In conclusion, A. brasilense adheres to wheat roots in significantly higher numbers than E. coli, and adhesion is rapid, weak, and depends on bacterial surface protein.

### Anchoring of A. brasilense Sp7 to wheat roots

In the anchoring assay, MPCL is replaced by NMF as incubation medium. It was previously shown that a high C/N ratio stimulates flocculation of A. brasilense in liquid culture, due to the production of a Calcofluor-binding fibrillar polysaccharide (Sadasivan & Neyra, 1985; Michiels et al., 1990). With the present assay, we wanted to test whether this polysaccharide would promote binding of A. brasilense to wheat roots. The anchoring kinetics in Fig. 1(b) suggest that this is indeed the case. Two binding phases can be clearly distinguished: a rapid adsorption in the first 2 h of incubation, and an additional binding phase initiating after 8 h of incubation and reaching a constant level of 11.1% of the initial inoculum after 16 h, corresponding to 1.7 × 10^7 bacteria per root. Binding of E. coli HB101, by comparison, is not biphasic and is about 70 times lower after 16 h of incubation. Bacteria anchored to wheat roots in this assay could not be released by vortexing in water or in 2.5 mM-EDTA (Table 2).

It can be concluded that, in the conditions of the anchoring assay, A. brasilense binds to wheat roots in two clearly separated phases. The first phase is a rapid and weak adsorption, as described above. The second phase is the firm anchoring of adsorbed and not yet adsorbed bacteria. Anchoring begins only 8 h after transfer of the bacteria to the NMF incubation medium. This suggests that anchoring depends on the synthesis of bacterial extracellular polysaccharides, which is rapidly induced in NMF, but not in MPCL medium.

### Results and Discussion

**Adsorption of A. brasilense Sp7 to wheat roots**

Fig. 1(a) compares the adsorption kinetics of A. brasilense Sp7 and E. coli HB101. Adsorption of the A. brasilense strain starts immediately (15 min or less) after addition of the bacteria to the root, and after 1.5 h reaches a level of 26% of the initial inoculum, which corresponds to 3.9 × 10^6 bacteria per root. No substantial further increase is seen for a period up to 20 h. Adsorption of E. coli remains at least 20 times lower during a 20 h incubation time.

The strength of adsorption of A. brasilense to wheat roots was tested by comparing the efficiency in removing adsorbed bacteria of three wash procedures of increasing stringency. Vortexing three times for 5 s in water or in 2.5 mM-EDTA reduced adsorption about 25-fold (Table 2).

Next, we treated labelled A. brasilense cells with pronase E (2 mg ml⁻¹; Sigma) for 2 h at 37 °C, removed pronase E by two washes in MPCL, and used the cells in our adhesion assay. Adhesion was reduced 20-fold, to a level comparable to E. coli HB101 adsorption. Viability of the cells was not affected by the pronase E treatment, as was shown by plating equal numbers of treated and untreated cells.

In conclusion, A. brasilense adheres to wheat roots in significantly higher numbers than E. coli, and adhesion is rapid, weak, and depends on bacterial surface protein.

**Anchoring of A. brasilense Sp7 to wheat roots**

In the anchoring assay, MPCL is replaced by NMF as incubation medium. It was previously shown that a high C/N ratio stimulates flocculation of A. brasilense in liquid culture, due to the production of a Calcofluor-binding fibrillar polysaccharide (Sadasivan & Neyra, 1985; Michiels et al., 1990). With the present assay, we wanted

* Cal refers to colony fluorescence on plates containing 200 µg Calcofluor ml⁻¹: Cal+, wild-type fluorescence; Cal^a, no fluorescence; Cal^−, dimmed fluorescence.
† Adsorption and anchoring are expressed as a percentage of the total number of bacteria incubated with the root (i.e. 1.5 \times 10^8). Each value is the mean ± standard deviation of 18 values obtained from three independent experiments with sixfold replications for each strain.

An *A. brasilense* mutant defective in adsorption, not in anchoring

As a part of our investigation on the functions encoded by the *A. brasilense* 90 MDa plasmid, we have constructed mutants carrying specific deletions in this plasmid (C. L. Croes and others, unpublished). In one of these mutants, Sp7 p90A084, adsorption to wheat roots was reduced 20-fold to a level comparable to *E. coli* HB101 (Ads^-) (Table 3). Since this mutant still produces the Calcofluor-binding polysaccharide, and still flocculates in NMF medium (C. L. Croes and others, unpublished), we expected it to have wild-type anchoring capability (Anc^+). This prediction was confirmed (Table 3). The existence of an Ads^- Anc^+ mutant shows that anchoring of *A. brasilense* to wheat roots does not require high numbers of adsorbed bacteria.

A. *brasilense* mutants defective in anchoring, not in adsorption

Previously, we reported the isolation and characterization of *A. brasilense* Tn5 insertion mutants that are affected in the production of the Calcofluor-binding polysaccharide. These mutants were classified according to the level of fluorescence of the bacterial colonies on agar plates containing Calcofluor: Cal^+ indicated wild-type fluorescence; Cal^a, dimmed fluorescence; Cal^−, no fluorescence. We also showed a direct correlation between the production of this Calcofluor-binding polysaccharide and the flocculation ability of the mutants, since Cal^- mutants did not flocculate at all, and Cal^a mutants showed reduced flocculation compared to the Cal^+ parent strain 7030 (Michiels *et al.*, 1990).

These mutants allowed us to test the hypothesis that
anchoring of *A. brasilense* to wheat roots would be mediated by this Calcofluor-binding polysaccharide. Indeed, it was found that the Cal and Cal mutants had at least 6-fold and 15-fold reduced anchoring capacity, respectively, compared to strain 7030, from which they were derived (Table 3). In addition, adsorption seems not to be significantly affected by the Cal mutations (Table 3). Thus the attachment phenotype of the Cal mutants is Ads\(^{+}\) Anc\(^{-}\).

**Conclusions**

We have provided evidence for the existence of two distinct modes of attachment of *A. brasilense* Sp7 to wheat roots. First, the binding kinetics in Fig. 1(b) clearly shown a biphasic pattern. Apart from the greater lag time, the second binding phase differs from the first in that binding is stronger than during the first phase. Also, first-phase binding can be eliminated by protease treatment of the bacteria prior to the assay. This suggests the involvement of bacterial surface components of a protein nature. For these reasons, we adopted the terminology adsorption (Ads) for first-phase binding, and anchoring (Anc) for second-phase binding. As opposed to adsorption, anchoring was shown to rely on a Calcofluor-binding surface polysaccharide, since mutants defective in the production of this polysaccharide are Anc\(^{-}\).

Adsorption and anchoring are two completely independent processes. This is already suggested by their dependence on two different bacterial surface components, but more rigorous evidence comes from the existence of both Ads\(^{-}\) Anc\(^{-}\) and Ads\(^{+}\) Anc\(^{-}\) mutants. These are the first *Azospirillum* attachment mutants reported. Both types of mutants also differ genetically, since the Cal mutants (Ads\(^{+}\) Anc\(^{-}\)) are all chromosomal mutants (Michiels *et al.*, 1982), whereas Sp7 p90A084 (Ads\(^{-}\) Anc\(^{+}\)) carries a deletion in the 90 MDa plasmid (C. L. Croes and others, unpublished).

In *Agrobacterium tumefaciens*, a similar two-step attachment process has been described (Matthysse *et al.*, 1981). In this plant pathogen, mutants defective in adsorption were all avirulent (Douglas *et al.*, 1982; Thomashow *et al.*, 1987; Matthysse, 1987), whereas anchoring mutants showed reduced virulence only when the plant inoculation site was washed with water (Matthysse, 1983). Thus, in natural conditions, anchoring can prevent *A. tumefaciens* from being washed from a wound site by rain. *In vivo* adsorption of *Azospirillum brasilense* to roots has been shown repeatedly (Umaligarcia *et al.*, 1980; Bashan *et al.*, 1986; Gafny *et al.*, 1986), but it is not clear whether this bacterium can also anchor under natural conditions like *Agrobacterium tumefaciens*. Scanning electron micrographs of roots inoculated with *Azospirillum* have revealed bacteria embedded on the root surface in a fibrillar matrix, but it has not yet been shown whether this matrix consists of bacterial polysaccharide or of root mucigel (Umaligarcia *et al.*, 1980; our laboratory, unpublished). Nevertheless, it seems evident that the ability of *A. brasilense* to rapidly adsorb and firmly anchor in high numbers to plant roots, and possibly also to soil particles, contributes to its competitiveness in root colonization. The availability of the above-described mutants for various in *vivo* inoculation experiments will allow this hypothesis to be tested.
