Effect of short-term variation in irradiance on light harvesting and photosynthesis of the marine diatom \textit{Skeletonema costatum}: a laboratory study simulating vertical mixing

JACCO KROMKAMP* and MARGA LIMBEEK

Netherlands Institute of Ecology, Centre for Estuarine and Coastal Ecology, Vierstraat 28, NL-4401 EA Yerseke, The Netherlands

(Received 7 September 1992; revised 15 April 1993; accepted 27 April 1993)

A laboratory study was conducted into the physiology of \textit{Skeletonema costatum} grown under a simple sinusoidal and a fluctuating light regime. The latter simulated a light regime similar to that which could result from the vertical mixing caused by Langmuir circulation. It was shown that the culture simulating vertical mixing reacted by decreasing the photosynthetic unit (PSU) size and increasing the number of PSUs, and hence optimized the rate of maximal photosynthesis at high, saturating irradiances. This culture also showed some change in photosynthetic parameters during the light period, which was especially pronounced during the shift from a low to a higher irradiance. The effect of this on estimates of primary production in a water column is discussed. Further, it is speculated that the assimilation number is regulated by the maximum light intensity experienced during the day rather than the total daily light dose, because only the culture submitted to a fluctuating light regime showed a real change in the maximum rate of photosynthesis \((P_{\text{max}})\) upon transfer to higher light levels.

Introduction

When primary production is estimated, the photosynthesis versus irradiance curve forms the basis for the calculation of phytoplankton production. The implicit assumptions made in this calculation are that the functional relationship between light and photosynthesis does not change in time when the algae are circulating through a light gradient in a mixed layer and that this relationship stays constant during the period of the measurement. Whether these assumptions are valid depends on the time scale of fluctuation in the physical environment and the time scale of change of the photosynthetic response. It is generally assumed that when the time scale of change is larger than the time scale of adaptation, phytoplankton will conform to a vertical gradient associated with the adaptation process (Reynolds \textit{et al.}, 1987; Cullen & Lewis, 1988).

It is well known that phytoplankton respond physiologically to changes in the ambient light field. For reviews on light-shade adaptation, see Harris (1978), Richardson \textit{et al.} (1983), Falkowski (1980). However, changes in the nutrient regime (Riegman \textit{et al.}, 1985; Kromkamp \textit{et al.}, 1989; Herzig & Falkowski, 1989; Kolber \textit{et al.}, 1988) as well as changes in the ambient light regime can cause alterations in photosynthetic parameters. We now have a reasonable understanding of the mechanisms causing changes in photosynthetic parameters from studies performed on photoadaptation. The problem is, however, that the best-documented studies were performed on algal cultures adapted to a particular set of environmental conditions. The major causes for the short-term variations in photosynthetic parameters are less well known, despite the numerous studies on short-term variations in irradiance (Marra, 1978; Neale & Marra, 1985). Nevertheless, a few studies report on the kinetics of photoadaptation (Post \textit{et al.}, 1984, 1985; Post, 1986; Cullen & Lewis, 1988) and it is clear from them that photoadaptation normally follows first order kinetics or, occasionally, a logistic function (Cullen & Lewis, 1988).

A number of questions remain. For example, in light-limited cultures, it is still unknown whether the increase in photosynthetic capacity observed when the growth
irradiance is reduced is due to a decreased light intensity or a lower total daily light dose causing a lower growth rate. This is because it is very difficult, in light-limited cultures, to separate growth effects from direct irradiance effects.

In this paper we describe the photosynthesis of light-limited continuous cultures of the marine diatom Skeletonema costatum, grown with a simple, sinusoidal light regime and with a fluctuating light regime simulating vertical mixing, both grown at identical dilution rate (i.e. equal growth rates). However, the total amount of light quanta received during the 24 h light-dark period was the same. This made it possible to separate the long-term from the short-term light effects. It will be shown that despite similar light doses, photosynthetic physiology was quite different.

**Methods**

*Organism and cultivation. S. costatum* was isolated by J. Rijstenbil from the 'Veere Meer', part of the Dutch Delta area. The organism was grown in a modified artificial medium with a salinity of approximately 14 g L⁻¹, according to Kester et al. (1967), which consisted of the following salts: NaCl, 327 mM; Na₂SO₄, 23 mM; MgCl₂, 45 mM; KCl, 72 mM; CaCl₂, 83 mM; KBr, 330 μM; NaNO₃, 59 mM; H₃BO₃, 178 μM; NaH₂PO₄, 50 μM; NaHCO₃, 2 mM; SrCl₂, 38 μM; Na₂SO₄, 150 μM; Na₂EDTA, 6.3 mM; FeCl₃, 10 μM. Trace metals: CuSO₄, 0.5 μM; KBr, 330 μM; NaCl, 186 mM; CoCl₂, 19 mM; NaN₃, 56 mM; Na₂SeO₃, 6 μM. Vitamins: thiamine (B₁), 74 μM; biotin (H), 100 nM; cyanocobalamin (B₁₂), 18 nM. The medium was sparged with air and after the pH was adjusted to 7.8 the medium was filter-sterilized (IVEX-2, 0.22 μm pore size, Millipore) by pumping it into autoclaved polycarbonate carboys (Nalgene).

The algae were grown in flat, 2 l cylindrical glass vessels with a light path length of 3 cm. In front of the vessel a water jacket was mounted to a temperature-controlled water bath to keep growth at 17 °C. The algae remained suspended by gently bubbling the cultures with water-saturated air. Nevertheless, sometimes limited cell lysis (< 5%) could not be prevented.

The light course was a 250 W (culture 1) or 400 W (culture 2, see below) high pressure lamp (Philips HPIT E40). The cultures were placed in a black box. In front of the culture facing the lamp a system of horizontal slats (Venetian blinds) was mounted. The position of the slats was altered by a step motor, controlled by a computer. Three serially aligned custom-built silicon light sensors were attached to the back or the front of the culture vessel. These sensors had an identical linear response over the range of irradiances used. The actual irradiance measured by the sensors was calculated with the irradiance measured (see below) and when necessary the position of the slats was adjusted (every 5 s). In this way the actual irradiance was always within 5% of the calculated value.

The average irradiance (I) in the culture was calculated as follows (Van Liere & Walsby, 1982):

\[ I = \frac{(I_0 - I_x)/\ln(I_0) - \ln(I_x)}{\ln(I_{m}) - \ln(I_{l})} \]  

where \( I_0 \) is maximum irradiance at noon, \( I_x \) is the irradiance at x time since sunrise (i.e. start light period) and \( I_{m} \) is the length of the light period in a 24 h light-dark (LD) cycle.

Culture 2 simulated vertical mixing, i.e. it was assumed that the average movement through the mixed layer to the depth could be described by a circular motion: this means that irradiance at a hypothetical vertical position can be described as a sine function of time and the number of cycles (nc) during the above-mentioned light period from the surface to the bottom of the mixed layer (\( z_n \)):

\[ z_n = 0.5z_{max}[1 + \sin(2\pi nt/LP - 0.5\pi nc)] \]  

where \( z_n \) is the depth (m) at time t. The irradiance at depth \( z_n \) is calculated using the Beer-Lambert equation:

\[ I_n = I_0 e^{-Kz_n} \]  

where \( Kz_n \) is the diffuse downwelling attenuation coefficient (m⁻¹). Of course, particle displacement by diffuse turbulent motion is more complicated than described here, but circular movement through the mixed layer can be caused by, for instance, Langmuir circulation (although mixing times are in general shorter than, see below). The use of equations 2, 3 and 4 makes it possible to simulate all sorts of light gradients in the mixed layer. During the first experiment both cultures were grown with a light period of 8 h and an average low light intensity (LL) of 30 μE m⁻² s⁻¹ [i.e. a total daily light dose (TDLD)] of 0.86 E m⁻². The peak irradiance (\( I_{max} \) of culture 1 was 47 μE m⁻² s⁻¹. Algae in culture 2, simulating vertical mixing, were assumed to move three times from the surface to \( z_{max} \) and back during the 8 h light period. Hence, the average time to traverse the mixed layer once from the surface to the bottom of the mixed layer was 80 min. Using the approach of Denman & Gargett (1983) one can calculate that this equals the mixing time of a mixed layer of 30-40 m depth with an average turbulent velocity generated by mild winds speeds (2-3 m s⁻¹).

The maximal irradiance in this culture was 167 μE m⁻² s⁻¹ (this higher peak irradiance was necessary to get similar TDLDs). The time course in average irradiance of both cultures is depicted in Fig. 1. After the steady state were measured, the light intensity was in one step doubled to a TDLD of 1.72 E m⁻² (referred to as high light (HL)), giving maximal irradiances of 200 and 320 μE m⁻² s⁻¹. During steady state the dilution rate (which equals growth rate in steady state) at LL was set at 0.07 d⁻¹ and for HL at 0.18 d⁻¹.

**Optical measurements.** Irradiances were measured with a cosine-corrected quantum sensor (MACAM SD101Q). This light meter was
also used to calibrate the silicon light sensors used in the continuous cultures. 

*In vivo* absorption of the algal cells was measured in a double-beam scanning spectrophotometer (Uvikon 940) according to the Shibata technique (Shibata et al., 1954) to minimize the loss of signal due to scattering: the cuvettes were close (1.5 cm) to the windows of the photomultiplier (PMT) and a light diffuser was placed between the PMT and the cuvette. Chlorophyll-specific absorption cross-sections \( [k_c \text{ m}^2 \text{ (mg chl)}^{-1}] \) were calculated from the absorption measurements and the chlorophyll concentration:

\[
k_c = \frac{[4 \times 100 \times \ln(10)]}{[\text{chlorophyll}]} \tag{5}
\]

where \( A \) is the *in vivo* absorption of the samples.

The optical cross-section of a single chlorophyll a molecule (\( \sigma_{chl} \text{ nm}^2 \)) can be calculated from the absorption cross-section \( k_c \) by changing the dimensions from \( \text{m}^2 \text{ (mg chl)}^{-1} \) to \( \text{nm}^2 \text{ (molecule chl)}^{-1} \).

**Photosynthesis measurements.** Photosynthetic oxygen evolution was measured in a chamber using a polargraphic oxygen electrode (YSI 5331) fitted with a water jacket to keep the temperature constant (17 ± 0.1°C) (Dubinsky et al., 1987). A slide projector with neutral density filters was used as a light source for photosynthesis measurements. Respiration was measured before the light measurements were done. Light was measured at the back of the chamber. The average irradiance in the chamber was measured as described by equation 1. Photosynthetic irradiance data, normalized to chlorophyll a, were fitted with an iterative least-squares method according to Eilers & Peeters (1988). The maximal photosynthetic capacity \( (P_{\text{max}}) \) is the maximum rate of photosynthesis \( [\text{mg O}_2 \text{ (mg chl)}^{-1} \text{h}^{-1}] \). Gross \( P_{\text{max}} \) values are presented here. The photosynthetic efficiency is the slope \( (\varepsilon^\text{B}) \) of the photosynthesis versus irradiance curve \( [\text{mg O}_2 \text{ (mg chl)}^{-1} \text{h}^{-1}] \). The subscript B in \( \varepsilon^\text{B} \) and \( P_{\text{max}} \) denotes that the photosynthetic parameters are expressed per unit chlorophyll a.

The photosynthetic unit (PSU) size, i.e. the number of chlorophyll a molecules necessary to produce one molecule of \( \text{O}_2 \), was determined by exposing a sample of known chlorophyll a concentration to a series of single turnover saturating flashes of different frequency (Myers & Graham, 1971; Dubinsky et al., 1986). A PSU is thus an oxygen-producing functional entity. The rate of oxygen production (being a linear function of flash frequency) was measured in the chamber described above. Because the flash unit (EG & G MVS 2601) was equipped with a storage capacitor, the energy of each xenon flash was constant. Flash duration was less than 10 µs, i.e. less than the turnover time of the \( \text{O}_2 \) and thus short enough to close photosynthetic reaction centres only once. The intensity of the flash was high enough to close all photosynthetic reaction centres. No background photosystem I (PSI) light (far red light) was provided because in diatoms the optical cross-section of PSI for xenon light is large enough (i.e. PSI-activity will not be rate-limiting. Dubinsky et al., 1986). When the rate of oxygen evolution [mol \( \text{O}_2 \text{ (mol chl)}^{-1} \text{s}^{-1} \)] is plotted against the flash frequency (s⁻¹), the reciprocal of the slope of the graph is equal to the PSU size [mol chl (mol \( \text{O}_2 \))⁻¹]. The slope was calculated using linear regression analyses. As four electrons have to be photoactivated to produce one molecule of oxygen, each PSU contains four PSI reaction centres.

The overall turnover time \( t \), (ms, i.e. the time necessary to move four electrons through one PSU and donate them to NADP) determines the rate of photosynthesis. \( t \) was calculated from the PSU size and \( P_{\text{max}} \) (expressed per minute) (Dubinsky et al., 1986):

\[
t = 600000 / (\text{PSU} \times P_{\text{max}}) \tag{6}
\]

The factor 60000 is a conversion factor (ms min⁻¹).

The optical cross-section of a PSU \( (\sigma_{\text{PSU}} \text{ nm}^2) \) was calculated as (Dubinsky et al., 1986):

\[
\sigma_{\text{PSU}} = \sigma_{\text{chl}} \times \text{PSU} \tag{7}
\]

The minimum quantum requirement [mol quanta (mol \( \text{O}_2 \))⁻¹] is the reciprocal of the quantum efficiency of photosynthesis \( (\Phi_P) \):

\[
1/\Phi_P = 115 \times k_c / x^8 \tag{8}
\]

where the constant 115 is needed to unify the dimensions of \( k_c \text{[m}^2 \text{ (mg chl)}^{-1}] \) and \( x^8 \text{[mg \text{O}_2 \text{ (mg chl)}^{-1} \text{h}^{-1} \text{(µE m}^{-2} \text{s}^{-1})^{-1}] \}.  

**Chemical analysis.** Pigments were measured in 90% (v/v) acetone and measured spectrophotometrically using the equations of Jeffrey & Humphrey (1975). Samples (4 ml) were spun down and sonicated three times for 10 s on ice in 10 ml 90% acetone. After adding another 6 ml of 90% acetone, the samples were put in the dark, at room temperature, for extraction. After spinning (900 g, 5 min) the supernatant was scanned. No chlorophyll could be extracted from the pellet.

**Transients states.** During the transient state from LL to HL the data were fitted to a first order kinetic equation (Falkowski, 1980; Post et al., 1984):

\[
P_t = (P_0 - P_e) e^{-kt} + P_e \tag{9}
\]

where \( P_t \) is the process parameter during the transient state at time \( t \), \( P_0 \) and \( P_e \) are the initial and final values for parameter \( P_t \), and \( k \) is the specific rate of adaptation having dimensions of h⁻¹. \( P_0, P_e, \) and \( k \) were estimated by non-linear least-squares regression using the software program SYSTAT for Windows (Version 5.0, Systat Inc. 1992, Evanstone, IL, USA).

**Results and Discussion**

**In vivo absorption cross-section**

Cells of the example shown (Fig. 2) grown under LL had different average \( k_c \) values of 0.0090 and 0.0073 m² (mg chl)⁻¹ for the cultures receiving a sinusoidal (1) and fluctuating (2) light regime, respectively. Since \( k_c \) was identical at 675 nm, the small differences in absorption cross-section cannot be due to differences in self-shading of chlorophyll by the thylakoids within the chloroplasts, but were more likely due to a small difference in pigment composition. The \( k_c \) of both cultures was measured several times at different days during the steady state. The average values (+95% confidence intervals) were

![Fig. 2. Absorption cross-section (\( k_c \)) of cells grown in LL (bold lines) or HL (thin lines). Solid lines, culture 1; dashed lines, culture 2.](image-url)
0.0087 (± 0.0003) and 0.0080 (± 0.0006) m² (mg chl⁻¹) for cultures 1 and 2, respectively, hence they were not significantly different. Our kₛ values were similar to those reported for S. costatum by Welschmeyer & Lorenzen (1981), but were higher than the 0.0038–0.0044 m² (mg chl⁻¹) reported for the marine diatom Thalassiosira weissflogii (Dubinsky et al., 1986; Post et al., 1985).

When the cells were grown under HL, the spectrally averaged kₓ of culture 2 rose from 0.0073 to 0.0114 m² (mg chl⁻¹), whereas kₓ of culture 1 remained constant (Fig. 2). The differences in kₓ at 675 nm indicated that self-shading of thylakoids both within and between the chloroplasts was decreased in culture 2 under HL. This increase in the package effect at lower growth irradiances is well documented (Morel & Bricaud, 1981; Osborne & Raven, 1986; Berner et al., 1989). When the kₓ of culture 1 is divided by the kₓ of culture 2 (Fig. 3) changes in pigment composition can be detected. As already discussed above, in LL the ratio relative to that at 675 nm is higher in the blue to yellow region, indicating that accessory light harvesting pigments were responsible for the slightly higher average cross-section of culture 1 during growth in LL. In contrast to the situation in LL, kₓ of culture 2 was uniformly larger than that of culture 1 (Fig. 3), indicating that the pigment composition of both cultures was the same in HL, but that the package effect was more pronounced in culture 1.

P_max, α²

Photosynthetic efficiency (α²) was not very dependent on the light intensity (Table 1). The small differences between the cultures grown in LL or HL were not significant. However, α² of S. costatum grown under a fluctuating light regime (culture 2) showed higher photosynthetic rates per unit chlorophyll than those from cells grown with the sinusoidal light regime. The maximal photosynthetic capacity in LL was slightly higher in culture 1 than in culture 2 (Table 1). This is reflected in the lower Iₛ value of culture 2 compared to that of culture 1. When the cells were grown with a higher irradiance (HL) P_max increased nearly threefold in the culture simulating vertical mixing, whereas the increase in P_max in culture 1 was rather limited. Iₛ values were similar for both cultures in HL. So, despite both cultures receiving identical TLDs in LL or HL, their photosynthetic parameters differed markedly.

As both cultures had the same dilution rate (i.e. the same growth rate when in steady state), different densities might be expected based on the different photosynthetic characteristics. To check this, we calculated the total amount of oxygen produced per mg chlorophyll a during the 8 h light period using the values quoted in Table 1. Photosynthesis was calculated every 5 min based on the following formulation to describe a photosynthesis light curve: Pₘₐₓ = P_max tanh (I/Iₛ) (Jassby & Platt, 1976). In LL culture 1 produced 1241 mg O₂ in the light period, whereas culture 2 produced 1022 mg O₂. In HL this was 1991 and 2310 mg O₂, respectively. These are surprisingly small differences considering the different photosynthetic parameters between culture 1 and 2. Apparently both cultures have ‘optimized’ their photosynthetic performance with regard to their light regime. It also explains why differences in biomass are very small (not shown) between both cultures when grown at the same growth rate.

Oxygen flash yields and overall photosynthetic turnover times

Photosynthetic capacity per unit chlorophyll is a function of the number of PSUs and the turnover time τ of the photosystems. As shown in Table 2, τ was similar for

both cultures in HL and did not change significantly when the cultures were transferred from LL to HL. Culture 1, however, showed an increase in $\tau$ upon the transfer from LL to HL. Our values for $\tau$ were three to four times higher than those reported for T. weisflogii (Post et al., 1985). Both cultures decreased with PSU size when grown at a higher irradiance. A similar decrease in PSU size with increasing growth irradiance was reported for different marine algae (Table 3). The PSU size we found for culture 1 for S. costatum was similar to that of T. weisflogii reported by Post et al. (1985). Dubinsky et al. (1986) reported larger PSU sizes for the same strain of T. weisflogii, grown under identical conditions as in the studies by Post et al.

A decrease in $\tau$ corresponds to the D-type strategy described by Richardson et al. (1983) (to which they fitted S. costatum), and which hypothesizes that changes in light climate are reflected in changes in PSU size ($\alpha$ expressed per cell did not change significantly in culture 2 upon a transfer from LL to HL). We indeed found a decrease in PSU size upon a shift from LL to HL, especially in culture 1 (Table 2). However, not only did the PSU size change, also the number of PSUs decreased from $6 \times 10^5$ to $4.4 \times 10^4$ per cell in culture 1 and from $4.5 \times 10^5$ to $2.8 \times 10^4$ per cell in culture 2. So, culture 1 had both larger and more PSUs per cell than culture 2. However, the cells themselves were also considerably larger in culture 1. Because we made no estimates of cell size, we cannot quantify this and hence were unable to express PSU size and number on a biovolume base.

The light regime had a remarkable influence on PSU size of S. costatum: the culture with the fluctuating light regime had a smaller PSU size than the culture with the sinusoidal light regime. Thus, the culture receiving fluctuating light responded by decreasing its PSU size and increasing the number of PSUs per unit chlorophyll.

As the package effect decreased in culture 2 in HL, the optical cross-section of a single chlorophyll molecule increased from 0.0114 nm$^2$ in LL to 0.0169 nm$^2$ in HL. No change occurred in $\sigma_{chl}$ in culture 1 between LL and HL. Because $\sigma_{chl}$ did not change in culture 1, the optical cross-section of a single PSU increased as the number of chlorophyll molecules in the PSU increased (Table 2). It can be seen that an increase in $\sigma_{PSU}$ is not necessary when the PSU size increases in culture 2. The decrease in PSU size is more than compensated for by the increase in $\sigma_{PSU}$ when the culture is grown in HL, resulting in a net increase from $13.24$ to $16.02$ nm$^2$ per PSU. These optical cross-sections of the PSUs were similar to those reported for T. weisflogii (Dubinsky et al., 1986).

**Minimum quantum requirements**

At low flux densities the probability that a photon hits a reaction centre that is closed by a previous hit is small. Therefore there is a linear relationship between photo-

Effect of a change in growth irradiance

The growth irradiance in cultures was increased from an average of 30 (LL) to 60 \( \mu \text{E} \text{ m}^{-2} \text{ s}^{-1} \) (HL) and the photosynthetic parameters followed. As noted above, \( \alpha^b \) did not change significantly and the changes in \( P_{\text{max}}^a \) and \( \tau \) were not large enough to allow analyses of the kinetics of the change in values of these two parameters. This was partly because the change in growth irradiance from LL to HL was not very large. Nevertheless, culture 2 showed changes in cellular chlorophyll content, \( \alpha^b \), \( P_{\text{max}}^a \), and PSU size (Fig. 4), whereas \( \tau \) remained more or less constant.

The cellular chlorophyll content decreased following first order kinetics (Fig. 4a). The decrease in pigment content mirrored the increase in \( \alpha^b \) (Fig. 4b). The adaptation rate constants \( (k \) values\) were indeed similar for both processes (Table 4). As the specific rate of decrease in the chlorophyll content was similar to the specific rate of increase in cell numbers (not shown), it can be concluded that chlorophyll was diluted by cell division and that it was not actively degraded. The same conclusion was drawn by Post et al. (1984) when \( T. \) weisflogii was subjected to a large change in irradiance. As \( \alpha^b \) also changed at the same rate, it seems likely that \( k_c \) changed with a similar rate constant. As \( \alpha^b = k_c \Phi_a \) (equation 8), the decrease in the package effect, causing \( k_c \) to increase, is to a large extent responsible for the change in \( \alpha^b \). \( P_{\text{max}}^a \) increased more rapidly than \( \alpha^b \) or the cellular chlorophyll content (Fig. 4c), but the decrease in PSU size was even
faster. This means that structural changes, i.e. reorganization of pigment complexes took place at a rate higher than the growth rate. As \( \tau \) did not change during the transient, changes in \( P_{\text{max}}^{b} \) should be due to changes in PSU size and number (equation 6). However, the change in PSU size was faster than the change in \( P_{\text{max}}^{b} \). A possible explanation for this might be a redistribution of pigments in the light-harvesting protein complexes of PSI and PSII.

**Diel patterns**

We investigated whether both cultures showed any diel pattern in photosynthetic performance. In neither of the steady-state cultures could any change in pigments be detected, hence the \( k_c \) values did not change during the day (data not shown). Culture 1 did not reveal any significant diel pattern in photosynthetic activity. Culture 2 (LL), however, showed some variation in photosynthetic properties during the day. The \( a^b \) and PSU size did not change significantly during the day, but the turnover time \( \tau \) and consequently \( P_{\text{max}}^{b} \), showed some diel activity: when the light intensity in the culture peaked (see Fig. 1), \( \tau \) decreased approximately 5 ms, causing an increase in \( P_{\text{max}}^{b} \) (data not shown). Because of this pattern, which was found two out of three times, \( P_{\text{max}}^{b} \) showed lower values at the start and at the end of the light period. When culture 2 was shifted from LL to HL a significant pattern of change in photosynthetic parameters, coinciding with the change in light intensity, was observed during the first 2 d of the transient state (Fig. 4). Both \( P_{\text{max}}^{b} \) and \( a^b \) increased when the culture irradiance increased and decreased again when the irradiance decreased. We calculated the effect of this change in photosynthetic parameters on a theoretical photosynthesis–depth profile (Fig. 5, see legend for details). As can be seen, the sample taken at the start of the photoperiod when the light intensity was still low showed a low primary production compared to the sample taken when the culture irradiance was high (approx. at \( t = 170 \) min, see Fig. 1). The latter sample was representative for a sample taken at the surface of a water column, whereas the sample taken at LL at the beginning of the photoperiod was representative for a sample taken at the bottom of the euphotic zone. Consequently, vertical mixing through a light gradient can cause, depending on the rate of mixing, a vertical profile in photosynthetic parameters. Such profiles have been observed in chlorophyll/\( P_{\text{max}} \) ratios in the New York Bight and off the coast of Hawaii (Falkowski, 1983), and in \( a^b \) and \( P_{\text{max}}^{b} \) in the Northwest Atlantic Ocean (Platt et al., 1992). The existence of vertical profiles makes it necessary to sample the mixed layer at several depths if an accurate estimate of the total primary production is to be achieved. In the example given (Fig. 5), the water column production of the surface sample is 50% higher than the sample taken near the bottom of the euphotic zone.

Notice that the observed trend in photosynthetic parameters during the light period is opposite to what might be expected according to light–shade adaptation theory. Platt et al. (1992) also mention changes in \( P_{\text{max}}^{b} \) with depth opposite to what might be expected on occasions. However, when our LL and HL cultures were compared, the changes in \( a^b \) and \( P_{\text{max}}^{b} \) were as expected and were thus as predicted by light–shade adaptation.

**Conclusions**

The results from this preliminary study on the possible effects of vertical mixing on the photosynthetic physiology of the marine diatom *S. costatum* clearly showed that the organism adapted to a fluctuating light climate by decreasing its PSU size and increasing the number of PSUs. This made it possible to profit from the high peak irradiances when it was mixed to the lake surface. This effect was especially pronounced in HL, though the overall quantum dose was still not very high.

When the cultures were transferred from LL to HL, only the culture in which vertical mixing was simulated showed a threefold increase in \( P_{\text{max}}^{b} \). Hence, neither the total daily light dose, nor the growth rate (as this was kept constant) determined the value of the chlorophyll-
specific maximal photosynthetic capacity. It is therefore tempting to conclude that in this diatom it is the value of the peak irradiance which determines, at least partly, $P_{\text{max}}$. As in both LL and HL the peak intensity was larger than $I_\text{d}$ the threshold must be higher. Photosynthesis is fully saturated at values higher than $I_\text{d}$, i.e. at $I_\text{opt}$. In LL neither cultures ever encountered irradiances higher than $I_\text{opt}$, but in HL in culture 2 the peak irradiances nearly equaled $I_\text{opt}$. So, we cautiously speculate that $P_{\text{max}}$ will change if fully saturating irradiances for photosynthesis are reached, but further research is needed.
