Chemical and immunological analysis of the 
Aspergillus fumigatus cell wall

Hyphal-wall preparations of Aspergillus fumigatus have been analysed by sequential treatment with KOH, nitrous acid and again with KOH. By acidification of the alkali-soluble extract, a polyglucose was precipitated which showed an X-ray diffraction pattern similar to that of (1 -> 3)-x-glucan. The remainder of the alkali-soluble fraction was precipitated with ethanol; it contained all the mannose, galactose and protein of the wall and, in addition, 62% of the amino sugars. This wall-associated glycoprotein, following SDS-PAGE and immunoblotting, reacted with antisera raised against several mycelial extracts of A. fumigatus. Sera from patients with aspergilloma have antibodies which recognize components of this glycoprotein. The glycoprotein nature of these antigens was shown by their ability to bind Lens culinaris lectin. In addition, the antigen/antibody binding could be disrupted by exposure of antigen to periodate oxidation, hydrolysis with dilute acid or pretreatment with a large excess of an endo-β-D-galactofuranosidase. The alkali-insoluble fraction consisted of a covalently linked glucan-chitin complex. Nitrous acid treatment, which specifically disrupts glycosidic linkages involving glucosamine, did not solubilize much material but changed the X-ray diffraction pattern from diffuse to a pattern showing the characteristic lines of crystalline (1 -> 3)-β-glucan and chitin. Most of the glucan became alkali-soluble after this treatment, and the insoluble residue appeared to contain crystalline chitin.

**Keywords:** Aspergillus fumigatus, cell wall, immunological activity

**INTRODUCTION**

The nature of the cell wall of Aspergillus fumigatus has received attention, partly because the potential of its surface structures as diagnostic antigens has long been recognized (Drouhet et al., 1972). Electron microscopy studies have shown that specific immunoglobulin from the serum of patients with antibodies to Aspergillus and from antisera raised in rabbits to A. fumigatus fractions bound almost exclusively to the mycelial cell wall (Hearn et al., 1991).

It is known from chemical analysis that the cell wall of Aspergillus contains predominantly glucan, chitin and galactomannan (Azuma et al., 1969). Water extraction of A. fumigatus mycelium yielded a glycoprotein with immunological activity (Azuma et al., 1968). We report here on the chemical and immunochemical analysis of components of the mycelial cell wall.

**METHODS**

**Organism and culture conditions.** A. fumigatus strain NCPF 2109 was grown in neutral glucose/peptone broth at 30 °C for 3 d. The mycelium was harvested by filtration, washed several times with water and stored at −20 °C until required.

**Preparation of cell walls.** The mycelial pad was thawed, suspended in 50 mM NH₄HCO₃ at pH 8-0 and disrupted with Ballotini beads, diameter 0-75–1.0 mm, at 5 °C in a Dynomill cell disintegrator. The cell homogenate was separated from the glass beads by decantation. The wall pellet was collected by centrifugation at 5000 g at 4 °C, washed several times with water and stored at −20 °C until required.

**Preparation of cell walls.** The mycelial pad was thawed, suspended in 50 mM NH₄HCO₃ at pH 8-0 and disrupted with Ballotini beads, diameter 0-75–1.0 mm, at 5 °C in a Dynomill cell disintegrator. The cell homogenate was separated from the glass beads by decantation. The wall pellet was collected by centrifugation at 5000 g at 4 °C, washed several times with NH₄HCO₃ buffer, washed finally with water and freeze-dried.

**Cell wall fractionation.** The wall preparation was extracted twice with 1 M KOH at 60 °C for 20 min under N₂. The alkaline extract was acidified with acetic acid to pH 5-0 and the precipitated material collected by centrifugation and washed with water. To the supernatant was added 2 vols ethanol. The

precipitate was collected by centrifugation and washed with 64% (v/v) ethanol. This was labelled the glycoprotein fraction. Both fractions were freeze-dried and stored at -20 °C until required. The alkali-insoluble material was washed several times with water, freeze-dried and stored at -20 °C. For the nitrous acid treatment the alkali-insoluble fraction obtained from 50 mg cell wall material was suspended in 1 ml water, 1.5 ml 2 M NaNO₃ and 0.5 ml 2 M HCl. The tube was closed tightly and shaken vigorously at room temperature for 1.5 h. On opening the tube, air was bubbled through (15 min) to remove the volatile nitrogen oxides. The insoluble material was collected by centrifugation, washed with water and extracted with 1 M KOH at 60 °C for 20 min. The extracted material was precipitated with 2 vols of ethanol, washed with 64% (v/v) ethanol and dried.

**Analytical methods.** Total carbohydrate content in hydrolysed and unhydrolysed samples was determined with the anthrone reagent (Fairbairn, 1953). Total hydrolysis was achieved by solubilizing the sample in 50% (v/v) formic acid in a boiling-water bath under N₂ for 15 min. Alternatively, the material was dissolved in 6 M HCl at 120 °C under N₂ for 15 min. Formic acid or HCl was then evaporated in vacuo over P₂O₅ and KOH in a desiccator. The residue was dissolved in 250 mM HCl and hydrolysis completed in the presence of Dowex 50 W-X8 (200-400 mesh) in the H⁺-form for 16 h at 100 °C. The Dowex was eluted with 1 vol. water to collect the neutral sugars and then with 5 vols 2 M HCl to collect amino sugars. Eluates were taken to dryness and dissolved in water. In hydrolysed samples total hexosamine was estimated by the method of Johnson (1971) and reducing sugars estimated using the method of Nelson & Somogyi (Nelson, 1944), while glucose and galactose were determined with glucose oxidase and galactose oxidase reagents, respectively (Boehringer Mannheim). Mannose was determined by subtracting the values for glucose and galactose from the value for reducing sugars, assuming that these three sugars were the only reducing sugars present. This was confirmed by TLC, which was done on a cellulose plate using, as solvent, pyridine/ethanol/water (5:1:1). Reducing sugars were visualized by spraying the plate with aniline phthalate reagent (Stahl, 1969).

Periodate oxidation was done by treating the alkali-soluble fraction with 15 mM sodium periodate at 4 °C in the dark for 48 h. The periodate consumption was followed by measuring the decrease in A₄₉₀. The glycoprotein fraction was treated with 50 mM sodium periodate at room temperature in the dark for 2 or 18 h. Protein was determined in the 1 M KOH extract using the Lowry method. The sensitivity to acid of the antigenic properties of the glycoprotein fraction was determined by treatment with dilute HCl (pH 2.0 at 100 °C for 20 min) and drying over KOH, prior to electrophoresis and blotting.

**X-ray diffraction.** X-ray diffraction patterns were obtained from powdered freeze-dried wall fractions. Spectra were recorded on a flat-film camera at a distance of 40 mm from the specimen. Ni-filtered Cu Kα radiation was used from a Philips fine-focus tube.

**Antigenic fractions from A. fumigatus mycelium.** Surface extracts solubilized in bicarbonate, a total water-soluble preparation, a protein-enriched (non-ConA binding) fraction and a carbohydrate-enriched (ConA-binding) fraction were obtained as reported elsewhere (Hearn & Mackenzie, 1979; Wilson & Hearn, 1983; Hearn, 1991).

**Rabbit antisera.** Antisera were obtained by hyperimmunization of New Zealand White rabbits. For the glycoprotein fraction amounts of 0.3 mg dry wt were used per injection, while for the predominantly carbohydrate antigen amounts of 10 mg dry wt were used per injection (Hearn et al., 1990).

**SDS-PAGE.** Vertical PAGE with a separating gel of 10% (w/v) polyacrylamide containing 0.1% (w/v) SDS was done according to Laemmli (1970). Samples for analysis were taken up in disrupting buffer (2%, w/v, SDS; 10%, v/v, glycerol; 5%, v/v, β-mercaptoethanol; plus a trace of bromophenol blue in Tris/HCl buffer, pH 6.8) and boiled for 10 min before application to the wells. High molecular mass protein standards (14-3-200 kDa; Gibco) were electrophoresed in parallel (Hearn et al., 1990). Separated components were stained for protein using 0.1% (w/v) Coomassie Brilliant Blue R-250.

**Electroblotting.** The electrophoretically separated molecules were electro-transferred to nitrocellulose membranes (Hybond C, Amersham) in a transblotting chamber (Towbin et al., 1979). Blots were stained for protein with India ink (0.1% in PBS/Tween 20) for 1 h at room temperature (Hancock & Tsang, 1983).

**Lectin treatment.** Lectins were chosen as probes on the basis of their specificity for selected sugar residues known to occur in A. fumigatus mycelium. ConA and wheat germ agglutinin (WGA) were peroxidase conjugates; Lens culinaris agglutinin (LCA) was biotin labelled. All lectins were purchased from Sigma. Details of the conditions for incubation are reported elsewhere (Hearn et al., 1989).

**Reactivity of antigens.** Sera at appropriate dilutions were incubated with transblotted antigens; antigen/antibody complexes were detected with anti-human or anti-rabbit IgG, peroxidase conjugated. The substrate for the peroxidase reaction was diaminobenzidine (Hearn et al., 1990).

**Enzyme treatment of glycoprotein.** A. fumigatus glycoprotein was incubated separately with two different hydrolases and with galactose oxidase following SDS-PAGE and transblotting. α-Mannosidase from jack bean (EC 3.2.1.24; from both Sigma and Boehringer Mannheim) was used at 50 U ml⁻¹ in 100 mM sodium acetate, pH 5.0, for 18 h at 37 °C (Zamze et al., 1991). Reactions using an exo-β-D-galactofuranosidase, prepared from Trichoderma harzianum, were kindly performed by A. W. van Bruggen-van der Lugt of the Agricultural University, Wageningen, the Netherlands. Briefly, blots were incubated in 200 mM sodium acetate, pH 5.0, for 16 h at 30 °C. The enzyme fraction contained 100 µg of protein, equivalent to 30 mU of enzyme. Blotted glycoprotein components were exposed to galactose oxidase (EC 1.1.3.9; Sigma) at 50 U ml⁻¹ in 100 mM potassium phosphate, pH 6.0, for 2 h at room temperature (Alon et al., 1991). Subsequent to enzyme treatments, blots were washed with PBS/Tween 20 and probed with homologous antiserum diluted 1:50.

**RESULTS**

**Composition of the hyphal wall**

The chemical composition of the hyphal wall of A. fumigatus is shown in Table 1. By using the anthrone reaction and glucose as the standard it appeared that 71.5% of the dry weight of the wall consisted of anthrone-reacting carbohydrate material. The monomeric composition was determined by TLC after complete hydrolysis of the wall; glucose, glucosamine, galactose and mannose were detected. The amounts of glucose and galactose were estimated by specific enzymic assays, and the mannose content was determined as the difference between the total carbohydrate value (anthrone) adjusted for the molar absorption ratios of galactose and mannose.
and the glucose and galactose values (glucosamine does not react with anthrone).

Completely hydrolysed walls consisted of 81.0% of reducing sugars, based on glucose as the standard. If the amounts of glucosamine, glucose and galactose were subtracted from this value, after adjusting for the molar absorption ratios of these substances, the amount of mannose was 3.5%, which is close to the value based on the anthrone assay.

Glucosamine was the only amino sugar detected in completely hydrolysed walls by a colorimetric assay as well as by TLC. Because the acetyl group is removed during hydrolysis, the amino sugar could be present in the native wall as both glucosamine and/or N-acetylglucosamine. Glucosamine-containing polymers are sensitive to nitrous acid treatment, which hydrolyses the glycosidic linkages between the glucosamine monomers converting them into 2,5-anhydromannose. Polymers of N-acetylglucosamine resist this treatment (Shively & Conrad, 1970; Datema et al., 1977). Treatment of the alkali-resistant fraction with nitrous acid (pH 3) removed 4.9% of the total amount of amino sugars, indicating that this could be present as glucosamine in the mature cell wall, with the remaining 95.1% as N-acetylglucosamine.

**Table 1. Composition of the hyphal wall of A. fumigatus**

Figures in parentheses represent the percentage of the complete fraction. Total carbohydrates were determined in unhydrolysed samples as anthrone-positive material; amino sugars were determined in hydrolysed samples; glucose was determined in hydrolysed samples with the glucose oxidase test; galactose was determined in hydrolysed samples with the galactose oxidase test; mannose was determined by subtracting the glucose and galactose values from the anthrone value; protein was determined in the alkali-extract with the Lowry test.

* Due to the interference of NO_3^- ions in several analytical tests, these values are calculated by subtracting the alkali-soluble and insoluble values from the values found in the complete fraction. The NO_3^- treatment was done by suspending the material in 1 M NaNO_3 at pH 3 for 1.5 h at room temperature.
† Second KOH extraction.

Composition of the alkali-insoluble fraction

After complete hydrolysis this fraction consisted entirely of glucose and glucosamine (Table 1). Nitrous acid treatment (pH 3) removed from the unhydrolysed fraction 53% of the amino sugars (which apparently were present as glucosamine) and 15.5% of the glucose.

Subsequent treatment of this fraction with 1 M KOH at 60 °C dissolved the rest of the glucan almost completely. Hydrolysis showed that it comprised of 91.1% glucose (Table 1) while X-ray diffraction analysis showed a pattern similar to hydroglucan [crystalline (1→3)-β-glucan] (Jelsma & Kreger, 1979). Fig. 1(C) shows the diffraction pattern before nitrous acid treatment and Fig. 1(D) the diffraction pattern after the nitrous acid treatment. The hydroglucan diffraction lines became more pronounced after this treatment and disappeared on subsequent alkali extraction (Fig 1E).

The fraction which remained alkali-insoluble after nitrous acid treatment consisted of 89-9% amino sugars (Table 1),

A, untreated wall; B, fraction soluble in alkali and precipitable with acetic acid; C, alkali-insoluble fraction; D, the same as C but treated with nitrous acid; E, the same as D but extracted with 1 M KOH. Asterisks indicate characteristic hydroglucan [(1→3)-β-glucan] spacings; vertical bars indicate characteristic chitin spacings; arrows indicate spacings characteristic for (1→3)-α-glucan. Probably N-acetylglucosamine because of its resistance to nitrous acid. In addition, it displayed an X-ray diffraction pattern which is characteristic of crystalline chitin (Fig. 1E).

**Immunological analysis of the alkali-soluble fraction**

The material extracted with 1 M KOH, following acidification and precipitation with ethanol, was solubilized in disrupting buffer for electrophoresis by SDS-PAGE. Separated components were stained for protein with Coomassie Blue, which revealed a major band doublet of apparent molecular mass 60–61 kDa (not shown). Following electrophoretic separation and subsequent transfer to a nitrocellulose membrane, this material was stained for protein with India ink. Bands with apparent molecular masses of 38, 60, 66 and 68 kDa were visualized by this procedure (Fig. 2, lane 1).

When this blot was treated with homologous antisera, raised in rabbits, a reaction was seen with the bands at 60, 66 and 68 kDa. In a total of ten batch preparations, these antigenic bands were quite reproducible. A representative sample is shown (Fig. 2, lane 2). That the antigenic epitopes were, in large part, carbohydrate in nature was shown by their susceptibility to periodate oxidation, which abolished much of their antigenic activity (Fig. 2, lanes 3 and 4). Pretreatment with dilute acid completely destroyed the antigenicity of these molecules (Fig. 2, lane 5). The glycoprotein nature of these molecules was further supported by their ability to bind to a lectin (LCA) with sugar specificity for α-D-glucose and/or α-D-mannose residues (Fig. 2, lane 6). Some additional components, of lower molecular mass, were also bound by this lectin. WGA and ConA did not bind to these molecules (results not shown). However, an antiserum raised in rabbits to a ConA-binding fraction of *A. fumigatus* water-soluble material bound specifically to the band doublet of...
DISCUSSION

The hyphal wall of *A. fumigatus* can be separated into several fractions by sequential alkali and acid treatment. Analysis showed a cell wall consisting of a glucan/chitin complex with similarities to the previously defined wall of *Aspergillus nidulans* (Bull, 1970). An alkali-soluble extract was obtained which was precipitated by acidification. This fraction consisted mainly of glucan and displayed an X-ray diffraction pattern similar to (1 → 3)-α-glucan (Kreger, 1954; Bacon *et al.*, 1968). This type of glucan has been reported to be present in several fungal species (Wessels & Sietsma, 1981).

Following removal of this glucan from the alkali-extract the remaining material was precipitated with ethanol. It appeared to consist of a gluco-galacto-manno-protein. On SDS-PAGE this glycoprotein complex showed major components of apparent molecular mass between 60 and 68 kDa which reacted with antibodies raised in rabbits against defined *A. fumigatus* extracts and with sera of patients with aspergilloma. The glycoprotein nature of these components was shown by their ability to bind to LCA with specificity for α-D-glucose and/or α-D-mannose residues. Failure to detect binding to ConA may be due to the lower sensitivity of peroxidase reagents in comparison with biotin-conjugated reagents.

Modification of some of the glyco- part of the glycoprotein by perioclate treatment removed much of the antibody-binding capacity. Antigen sensitivity to a β-galactofuranosidase implicates galactose residues in this reaction. However, a large excess of this enzyme was required to destroy antigen/antibody binding (cf. Van Bruggen-Van der Lugt *et al.*, 1992), and this enzyme is contaminated with small amounts of glucanase and exo-α-D-mannanase (De Ruiter *et al.*, 1994). These results and reactivity towards antisera raised to carbohydrate and protein components of *A. fumigatus* indicated that both of these types of structures are antigenic. Components with similar epitopes are probably excreted into the medium or loosely attached to the outer wall as water-soluble material (Hearn *et al.*, 1990).

The alkali-insoluble fraction consists of a glucan/chitin complex which seems to be present in almost all fungal species and probably plays a dominant role in fungal morphogenesis (Sietsma & Wessels, 1991). Following treatment with nitrous acid, most of the glucan that was initially alkali-insoluble became soluble in KOH. Nitrous acid is thought to specifically disrupt glycosidic linkages involving glucosamine. We therefore conclude that in this organism the glucan is linked to chitin through a linkage in which glucosamine is involved. N-Acetylglucosamine seems also to be involved because a portion of it (16±4%) of the amount present in the alkali-insoluble fraction becomes alkali-soluble after nitrous acid treatment and thus does not show properties characteristic of genuine chitin, which remains alkali-insoluble after nitrous acid treatment. In *Schizophyllum commune* it was shown that beside these amino sugars, some amino acids, especially lysine, seemed also to be involved in the linking of glucan to chitin. However, the exact type of linkage was not
elucidated (Sietsma & Wessels, 1979). In *Candida albicans* a (1→6) linkage was found between glucose and N-acetylglucosamine (Sararit et al., 1988) which could be part of this linkage. Again the exact nature of this linkage is still speculative. It is possible that different fungal species may use different types of linkage.

In general it is found that the glucan in the alkali-insoluble part of the hyphal wall of fungi not only contains (1→3)-β linkages but also (1→6)-β linkages. The presence of the latter linkage type was not further investigated in this study; however the detection of hydroglucan X-ray diffraction lines in untreated wall preparations (Fig. 1) indicates that the glucan chains are arranged in such a way that they are able to form triple helices stabilized by H-bridges (Jelsma & Kreger, 1979). This suggests that if (1→6) linkages were present, they are unlikely to be abundant. To date the only report of walls containing a (1→6)-β glucan consisting exclusively of (1→3)-β linkages is for those of *Didymella bryoniae*, a pathogen of cucumber plants (van Pelt-Heerschap & Sietsma, 1990).

The results of this study also show that crystallization of the (1→3)-β-glucan and chitin is hampered by the covalent linkages to each other. When these linkages are broken by nitrous acid, both substances become more crystalline, as shown by a more pronounced X-ray diffraction pattern.

The amino sugars [(N-acetyl)glucosamine] in the wall play different roles: 7-6% are alkali-soluble and are probably part of a glycoprotein; a small proportion, 4-9%, can be removed by nitrous acid and is therefore present in the form of glucosamine; after nitrous acid treatment 16.4% become alkali-soluble indicating that they are separated from the poly-N-acetylglucosamine main chains by a linkage containing glucosamine; the remaining 72.3% display properties corresponding to α-chitin.

The apparent involvement of glucosamine in the linkage of glucan to chitin in this organism is remarkable. In *A. nidulans* and *Neurospora crassa* it was shown that deacetylated amino sugars do not play a significant role (Mol et al., 1988). In the yeast species *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* (Mol & Wessels, 1987; Sietsma & Wessels, 1991), and also in some basidiomycetes, e.g. *Schizophyllum commune* and *Agaricus bisporus*, the involvement of glucosamine was inferred (Wessels et al., 1989). Larger amounts of deacetylated glucosamine (chitosan) generally occur in the hyphal walls of zygomycetes (Kreger, 1954; Datema et al., 1977; Davis & Bartnicki-Garcia, 1984). Chitosan is also present in the walls of the ascospores of *Sacb. cerevisiae* in considerable amounts (Briza et al., 1988). It could be that this partly deacetylated chitin is a more general phenomenon, important in the process of polysaccharide inter-linking.
