The Biolog microtitre plate assay, which is based on tetrazolium dye reduction as an indicator of sole-carbon-source utilization, has been evaluated as a rapid method to investigate the biodegradation of five classes of anionic surfactant by pure and mixed cultures of bacteria. The assay gave reproducible results over a fourfold range of inoculum optical density, and the surfactant concentration was selected to provide a compromise between the length of the lag period prior to colour production and the maximum colour produced. A kinetic model was developed and used to analyse the appearance of colour in the assay and was found to give rise to three biologically significant parameters describing the processes underlying the assay. No false-positives were obtained with environmental isolates. The small number of false-negatives obtained (< 8% of the total) could be explained by the methodology used to prepare the bacterial inoculum. All isolates which were positive in the Biolog assay were shown to be both primary and ultimate degraders of the test surfactant. These results show that the method provides a useful means of studying the biodegradation of anionic surfactants by both pure and mixed cultures of bacteria and will find use in the rapid analysis of biodegradation kinetics and specificities of larger numbers of individual isolates than hitherto possible. In addition, an important benefit of the methodology is that it can be used for direct analysis of the biodegradation potential of whole bacterial communities without having to make an artificial selection during laboratory growth.

Keywords: Biolog assay, microtitre plate, screening bacteria, surfactant biodegradation

INTRODUCTION

World production of synthetic surfactants in 1991 was 7 million metric tons, of which 1.8 million metric tons were anionic surfactants (Hauthal, 1992). Irrespective of their initial usage, the vast majority of these surfactants eventually reach waterways, either directly or via domestic sewage treatment works, in which microbial populations are responsible for their biodegradation.

Previous methods used to study the microbial biodegradation of anionic surfactants include isolation and characterization of the enzymes involved (Bateman et al., 1986; Cloves et al., 1980; Shaw et al., 1980) and the analysis of biodegradation kinetics in shake-flask die-away experiments (Anderson et al., 1990) in which surfactant is exposed to micro-organisms in a closed system and its disappearance monitored over time. While these methods can provide useful indications of the biodegradative capacity of pure and mixed bacterial cultures, each is limited by the complexity of the procedures which renders them useless for large-scale screening of the indigenous microflora responsible for anionic surfactant biodegradation.

The work of Bochner & Savageau (1977) showed that tetrazolium dye reduction could be used as a generalized...
available microtitre plate-based assay, the Biolog MT
plate (Bochner, 1989a, b). The assay is performed in a
standard 96-well microtitre plate, each well of which
contains the necessary redox chemicals, buffers and
nutrients in a dried film. The procedure (Biolog Inc.,
1993) requires the addition of the test carbon source
followed by inoculation with the test organism.
Mineralization of the test substrates gives rise to an
increase in reducing equivalents in the bacteria which in
turn irreversibly reduce the Tetrazolium Violet dye giving
rise to the purple colour characteristic of a positive Biolog
assay. The principal advantage of this assay over con-
ventional techniques is the ability to assay many organisms
and/or carbon sources using a single microtitre plate. For
example, this was exploited by Garland & Mills (1991)
in their use of Biolog plates containing 95 different carbon
sources (viz. the commercially available Biolog GN
microtitre plate) to classify and characterize whole mi-
crobial communities on the basis of their patterns of sole-
carbon-source utilization.

Whilst the Biolog MT plate is a relatively new tool for use
in biodegradation studies, its use is increasing. It has been
used to screen bacteria from such diverse environments as
Kraft-pulp effluent-treatment plants (Vicario et al.,
1993a, b) and terrestrial sub-surface sites (Lee et al.,
1992), for their biodegradative abilities towards a wide variety
of compounds, including chlorinated aromatics (Vicario et al.,
1993a, b), isocyanate-based biodegradable polymers
(Odocha et al., 1994), and a range of volatile and non-
volatile toxic organic compounds (Strong-Gunderson
et al., 1992; Gordon et al., 1993). While all these authors have
obtained meaningful results utilizing Biolog MT plates,
none has validated the data obtained with the
Biolog assay against more traditional methods.

In this paper we report the development of the Biolog MT
plate assay to screen pure and mixed bacterial cultures for
their ability to biodegrade five classes of sulphated and
sulphonated anionic surfactants. The results of this
application have been validated against accepted methods
of assaying both primary and ultimate biodegradation of
such compounds.

METHODS

Materials. Biolog MT Microplates were purchased from Biolog
Inc. (Hayward, CA 94545, USA) and stored at 4 °C. Bacto-
peptone and Casamino Acids for use in medium M were
obtained from Difco. Methylene Blue vital stain grade C.I.
5201 5 for use in the methylene-blue-active substance (MBAS)
assay was purchased from Merck. Ultrapure water for prep-
paration of all assay solutions was obtained by passing glass-
distilled water through a Millipore Milli-Q50 unit to give
18 MΩ resistivity water.

The following examples of five classes of anionic surfactant
were used in this study. SDS specially purified for biochemical
work (Merck) and sodium nonyl sulphate (SNS; Lancaster
Synthesis Ltd) were selected as representative primary linear
alkyl sulphates (PLAS). Potassium undecan-2-yl sulphate, a
secondary linear alkyl sulphate (SLAS), was synthesized by the
method of White et al. (1980) and shown to be > 99% pure
(determined by 1H- and 13C-NMR). The primary alkane
sulphonate (PANS) sodium 1-dodecane sulphonate was pur-
chased from Lancaster Synthesis Ltd. A commercial alkyl
ethersulphates (AES) formulations, Empicol ESB70, contain-
ing approximately 70% (w/w) alkyl ethoxy sulphates (with
alkyl chain lengths from C₉ to C₁₄ with mainly two ethoxy
units), 3-5% unsulphated alcohol ethoxylate, 1-5% sodium
sulphate, 0-3% sodium chloride and the balance as water, was
donated by Albright and Wilson. A commercial formulation
of alkylbenzene sulphonates (LABS), Nansa HS80/S, contain-
ing approximately 80% (w/w) sodium dodecyl benzene
sulphonate), 1-7% unsulphated dodecylbenzene, 3-8% so-
dium tripolyphosphate, 12% sodium sulphate and the balance
as water, was also donated by Albright and Wilson. The
commercial mixtures (AES and LABS) were deliberately
included despite their non-surfactant impurities, to show that
the method is equally valid for both pure surfactant components
and commercial formulations. The important feature about the
composition of the commercial materials is that they contain
minimal amounts of non-surfactant organic material which
would otherwise influence respiration activity in the Biolog
plates. All other chemicals were of analytical grade supplied by
Merck or Fisons Scientific.

Culture media. Medium M, an agar-containing non-selective
growth medium based on the casein-peptone-starch (CPS)
medium of Jones (1970) and supplemented with glycerol
(Burton et al., 1982), was used for the growth of environmental
isolates. Liquid medium M was obtained by omitting agar and
supplementing with 0-2% (w/v) bacto-peptone. In some
experiments when screening environmental isolates for their
surfactant-degrading capabilities, medium M was supplemented
with a mixture of surfactants.

Minimal medium for the isolation and growth of bacteria with
surfactant as the sole carbon source had the following com-
position (1 g L⁻¹): K₂HPO₄, 1.5 g; KH₂PO₄, 3 g; NH₄Cl, 0.5 g;
NaCl, 0.5 g; MgCl₂·6H₂O, 0.15 g; Na₃PO₄, 0.14 g; trace

elements solution, 1 ml. When required, the medium was
solidified with 15 g Type 1-A Agarose (Sigma). This base
medium was sterilized by autoclaving at 121 °C for 20 min,
cooled to 50 °C and amended with one of the following filter-
sterilized surfactants at the indicated final concentrations:
PLAS, 4 mM SNS; AES, 3 mM Empicol ESB70; SLAS, 3-5 mM
potassium undecan-2-yl sulphate; PANS, 3-5 mM
sodium 1-dodecane sulphonate; LABS, 3 mM Nansa
HS80/S. Concentrations of Empicol ESB70 and Nansa
HS80/S are stated as molar concentrations of the pure surfactant
calculated using the manufacturer's data for mean molecular
mass and percentage purity.

Bacterial strains. Escherichia coli strain JM101 (ATCC 33876,
NCIMB 11926) was used as a representative non-surfactant-
degrading organism and maintained on nutrient agar.
Pseudomonas C12B (ATCC 43648, NCIMB 11753), originally
isolated for its ability to mineralize SDS (Payne & Feisal,
1963) and recently identified as Ps. aeruginosa (unpublished results),
was used as the known degrading organism for PLAS.
Organisms capable of growth on the four other classes of
surfactant were obtained by standard enrichment techniques
using activated sludge as the inoculum. Single, pure isolates
were obtained for AES, SLAS and PANS, and these were
maintained by twice-weekly subculture on solid minimal
medium containing the respective surfactant as sole carbon
source. A four-membered consortium capable of mineralizing
LABS was obtained, no single member of which was able to
grow on solid medium containing Nansa H580/S as the sole
carbon source. This consortium was maintained by twice-
weekly subculture in fresh liquid minimal medium containing
Surfactant die-away test. Aliquots (76 ml) of autoclaved liquid minimal medium in 250 ml Erlenmeyer flasks were amended with filter-sterilized surfactant to give a final concentration of 80 μM. An inoculum was added and the flasks were incubated at 30 °C in a gyratory incubator at 150 r.p.m. At intervals, 2 ml samples were removed and frozen at −20 °C for later assay of MBAS.

Small-scale die-aways were performed in sterile, capped, polystyrene test-tubes (100 mm × 18 mm) containing 5 ml medium. Samples (1 ml) were removed at the beginning and end of the die-away and frozen at −20 °C for later MBAS assay to determine the total loss of MBAS during the die-away.

MBAS assay. The method was essentially that of Hayashi (1975), as modified by Thomas (1987). Assays were performed in nitric-acid-washed, optically matched test tubes. Results were calculated as percentage loss of original MBAS.

Biolog methodology. The manufacturer's standard methodology is as follows (Biolog Inc., 1993). (a) Grow bacteria on a non-selective solid medium. (b) Prepare, within the standardized OD range, a uniform suspension of cells in sterile, normal (0.85% w/v) saline. (c) Add test substrate to each well in a volume of 15 μl. (d) Inoculate the cell suspension (135 μl per well) into the Biolog plate. (e) Incubate the plate under appropriate conditions. (f) Analyse the colorimetric changes by eye or by measurement of absorbance, A.

This standard methodology was modified for use in the present study as follows. (a) Our experience has shown that many bacteria isolated during studies of surfactant biodegradation grow into solid media forming effuse colonies, making their subsequent removal for resuspension difficult. Therefore, the isolates in this study were grown to the mid-exponential phase of growth in liquid medium in shake-flasks at 30 °C. Bacteria were harvested by centrifugation at 3000 g, for 10 min and washed in 0.85% NaCl in 10 mM sodium phosphate buffer, pH 7.2. All solutions were maintained at 30 °C to avoid cold-shocking the bacteria. Centrifugation and washing were repeated twice. (b) The final bacterial pellet was resuspended in PBS and the absorbance of the resultant bacterial suspension adjusted to give an absorbance, A, of approximately 0.4 using a Novaspec II spectrophotometer (LKB Pharmacia) measuring against a PBS blank. This value corresponds to approximately 5 × 10^8 bacteria ml⁻¹. (c) Test surfactants were dissolved in 10 mM sodium phosphate buffer, pH 7.2, at twice final concentration, and 75 μl added per well. To correct for endogenous respiration and the carry-over of carbon from the bacterial cultures, corresponding blank wells (i.e. containing no test surfactant) were prepared containing 75 μl 10 mM sodium phosphate buffer, pH 7.2. (d) The standardized bacterial suspension was added to the plate (75 μl per well). (e) The plate was incubated at 30 °C without agitation. (f) To correct for the interference arising from the absorbance of bacteria and any precipitates formed in the wells, the plates were read in an Anthos 2001 microtitre plate reader (Denley Instruments), under computer control, using a measurement wavelength of 590 nm and a reference wavelength of 650 nm. The results produced by the plate reader were in the form of A - A, which represents the true purple/blue color produced as a positive result in the Biolog assay. The resultant absorbances were used to calculate the net Biolog colour which was defined as follows:

Biolog colour = \[ \frac{(A_{590} - A_{650})_{test \ well} - (A_{590} - A_{650})_{blank \ well}}{1000} \]

Thus Biolog colour represents the net increase in absorbance produced by metabolism of the added test surfactant.

The time-dependent changes in Biolog colour were calculated by subtraction of the time zero value. Positive values of Biolog colour represented biodegradation of the test surfactant, i.e. the colour in the test well exceeded that in the blank well due to an increase in respiration as a result of biodegradation of the test surfactant. A value of zero represented no biodegradation of test surfactant. It was assumed that a negative value meant that the test surfactant was inhibitory to the test isolate, so the level of endogenous respiration in the blank well exceeded that of the test well, giving rise to more colour in the blank well than in the test well.

RESULTS

Kinetic modelling of Biolog colour production

Tests were carried out with three versions of a logistic kinetic model, i.e. one where an initially growth-accelerated increase in the colour production becomes limited by exhaustion of a substrate. Two of these models were four-parameter and five-parameter models included in the non-linear regression package (SigmaPlot for Windows V1.02 from Jandel Scientific) used to curve-fit the data, and the third was a modification of the logistic growth curve proposed by Zwietering et al. (1990). The data were found to be modelled most accurately by the Zwietering equation which has the added advantages that its parameters are fewer in number (three) and they also have biological relevance. This model describes the Biolog colour, A, developed at time, t, as:

\[ A = \frac{A_{max}}{1 + \exp \left( \frac{4t}{t_{max}} - (t - \frac{2}{3}) \right)} \]

This kinetic model gives rise to three biologically

![Fig. 1. The kinetics of colour appearance in the PLAS Biolog assay of Pseudomonas C128 grown on medium M containing 1 mM SNS. The solid line is the line of best fit arising from the non-linear regression fitting of the logistic kinetic model to the experimental data (○).](image)
significant parameters: $A_{\text{max}}$, the asymptote or maximum colour produced; $\mu_m$, the maximum rate of colour production; and $\lambda$, the lag period prior to the rapid production of colour. Fig. 1 illustrates the application of a curve-fitted line for one set of data arising from Pseudomonas C12B grown on medium M containing 1 mM SNS, to give an inoculum $A_{390}$ value of 0.4, and assayed with 2.5 mM SDS over a time-course of 48 h. The estimates of the parameters arising from the curve-fitting process for these data were as follows: $A_{\text{max}}$, 212.49; $\mu_m$, 11.65 h$^{-1}$; $\lambda$, 11.24 h. The relatively small value (408.03) for the residual sum of squares which was obtained (relative to other kinetic models which were tested), together with visual inspection of the goodness of fit, suggested that this model was an accurate representation of the kinetics of Biolog colour appearance with time.

Optimization of surfactant concentration in the Biolog assay

The manufacturer's standard methodology (Biolog Inc., 1993) recommends a test-substrate concentration of between 20 and 200 p.p.m. It was decided to optimize the concentration of each surfactant class in the assay and to observe the effect of growth of the degrading organism on either minimal medium with surfactant as sole carbon source.
Table 1. Estimated kinetic parameters arising from application of the logistic kinetic model to the data in Fig. 2, illustrating the effect of surfactant concentration on colour production in the Biolog assay

The data are presented as means ± asymptotic standard errors generated by the non-linear regression process. See text for an explanation of the parameters.

source or on medium M containing a low concentration of a surfactant. The results for PLAS are illustrated in Fig. 2. The data in Fig. 2 were fitted to our modified logistic kinetic model and the resultant parameters are shown in Table 1.

There was no significant difference between colour production for Pseudomonas C12B grown on minimal medium containing 4 mM SNS and for Pseudomonas C12B grown on medium M containing 1 mM SNS. In either case, increasing the concentration of SDS increased the maximum rate of colour production (μm) and the maximum Biolog colour produced (A_max) but also increased the length of the lag period prior to the accelerated appearance of colour. To obtain a compromise between the length of the lag period and both the amount and rate of Biolog colour production, 2.5 mM SDS was selected as the optimum concentration for the assay. The non-degrader E. coli JM101 yielded much longer lag periods (Fig. 2 and Table 1) before the onset of colour production. At the selected concentration of 2.5 mM SDS, E. coli JM101 produced the longest lag and slowest colour production observed. We attribute the false-positive colour production in E. coli JM101 to bacterial
ysis in the presence of surfactant, thus releasing carbon to increase the metabolism of the remaining intact viable cells; a concentration of 2.5 mM SDS minimized such false-positives.

This experiment was repeated for the other classes of surfactant and similar results were obtained (data not shown). The optimum concentration for SLAS, PANS and LABS was found to be 2.5 mM and for AES it was 2.0 mM. With the exception of LABS-containing medium, the difference in colour production for the degrading organism grown on the two different media was not significant: thus, it was decided to grow environmental isolates for Biolog assay on medium M amended with low concentrations of surfactant. The colour production in the LABS assay using the consortium grown on medium M containing 1 mM NANSA HS80/S was low and not readily reproducible. It was necessary, therefore, to use the consortium grown on NANSA HS80/S as the sole carbon source in later experiments. The other known degraders were grown on medium M supplemented with the relevant surfactant.

**Effect of inoculum size**

The effect of inoculum size was investigated by assaying *Pseudomonas* C12B grown on medium M containing 1 mM SNS using inocula with $A_{590}$ values of 0 (i.e. PBS only), 0.1, 0.2 and 0.4 (the Biolog recommended value) and

![Fig. 3. Comparison of colour production in Biolog assay with surfactant die-away for five classes of surfactant: PLAS, AES, SLAS, PANS and LABS. The known degrading organism for each surfactant is shown as a filled circle.](image-url)
analysing the kinetics of the resultant data by application of the modified logistic model of Biolog colour appearance. Data for the PBS blank \( (A_{590} = 0) \) showed that no significant amount of Biolog colour was produced spontaneously without the presence of bacterial cells. On increasing the inoculum \( A_{590} \) value from 0·1 to 0·4, the lag period \( \lambda \) decreased from 13·07 ± 1·12 to 10·90 ± 0·84, a change of 17%. The values of \( \mu_m \) and \( \lambda_n \) were constant within the standard errors. These relatively small changes in the kinetic parameters arising from a fourfold change in \( A_{590} \) show that it is unnecessary to adjust the inoculum \( A_{590} \) value accurately to 0·4; isolates may therefore be assayed even if their growth is slow and/or does not reach high absorbances during inoculum growth.

**Isolation and screening of environmental isolates by Biolog assay with five classes of surfactant**

Environmental isolates were obtained by plating serial dilutions of epilithic bacteria on medium M agar. Epilithic bacteria were obtained by resuspension of the biofilm on a flat stone taken from a site in a polluted South Wales river, using the method of Burton et al. (1982). The site chosen was directly beneath the outfall from a municipal sewage treatment plant. Such sites are known to be relatively rich in bacteria capable of biodegrading anionic surfactants (Anderson et al., 1988). Thirty isolates were selected at random and transferred to fresh medium M plates for axenic growth.

Each isolate was inoculated from axenic plate culture separately into a 5 ml aliquot of medium M containing a mixture of the surfactants (0·1 mM each of SNS, Empicol ESB70, potassium undecan-2-yl sulphate, sodium 1-dodecane sulphonate and NANSA HSSO/S) in capped glass test-tubes (125 mm × 16 mm). Isolates were incubated for 18 h at 30°C in a gyratory incubator at 150 r.p.m. Each isolate was harvested by centrifugation and washed three times with PBS and the final bacterial pellet resuspended in PBS to give an \( A_{590} \) value in the range of 0·1–0·4. The five known degraders were grown on medium M supplemented with their respective surfactant and *E. coli* JM101 was grown on nutrient broth, all to mid-exponential phase and harvested according to this method.

The 36 isolates (i.e. 30 environmental isolates, 5 known degraders and *E. coli* JM101) were Biolog-assayed with each of the five classes of surfactants as shown in Table 2. Biolog colour was measured at 8 h intervals for a period of 64 h for the assays with PLAS, AES and SLAS, and at 12 h intervals for a period of 132 h for the assays with the more recalcitrant PANS and LABS. Preliminary experiments had shown that the maximum difference in Biolog
Colour between surfactant-degrading and non-degrading isolates occurred after 48 h for PLAS, AES and SLAS, after 108 h for PANS and after 132 h for LABS.

Comparison of Biolog colour production with surfactant die-away

Each of the 36 isolates was assayed for primary biodegradation of the same five classes of surfactant using small-scale die-away tests. A set of 37 die-away tubes containing 80 μM SDS was inoculated (5%, v/v) individually with each of the 36 isolates, prepared according to the Biolog protocol. The 37th tube was inoculated with PBS to act as a sterile control. Four further sets of 37 die-away tubes were prepared, each set containing one of the four other surfactants used in the Biolog assay, and inoculated as for the SDS tubes. The die-away tubes were incubated at 30 °C in a gyratory incubator at 150 r.p.m. The times for the known surfactant-degrading organisms to decrease the original concentration of the respective surfactant by approximately 95% had been determined previously (PLAS, 12 h; AES, 12 h; SLAS, 12 h; PANS, 60 h; LABS, 75 h) and samples were taken from the corresponding sets of die-away tubes at these times and frozen at −20 °C. All samples were assayed subsequently for MBAS, and the percentage loss of MBAS during the course of the die-away was calculated. These data have been compared with the corresponding production of Biolog colour in Fig. 3.

Comparison of Biolog colour production with growth on surfactant

Each of the 36 isolates previously Biolog-assayed with the five classes of surfactant was assayed for its ability to grow on each of these surfactants. Each isolate was inoculated on five agarose plates of minimal medium, each containing one of the five classes of surfactant at the concentration used previously to isolate the known degraders. The plates were incubated at 30 °C for 7 d and bacterial growth was estimated visually and scored: 0, no growth; 1, poor growth; 2, good growth. These data are compared with the Biolog assay data in Fig. 4. There are no data for LABS because, as discussed above, no single isolate was able to grow on this surfactant as sole carbon and energy source.

DISCUSSION

The majority of previous studies utilizing the Biolog methodology have involved measuring the Biolog well absorbances after a single, predetermined time, and little or no attention has been paid to the time dependency of colour development. Garland & Mills (1991) investigated the appearance of Biolog colour with time and their results suggest that the kinetics of colour appearance give rise to a sigmoidal curve resembling the classic bacterial growth curve. Our results confirm this and we have shown that the appearance of Biolog colour with time may be adequately described by a modified logistic growth model. Parameter estimates from non-linear regression of experimental data fitted to this model proved useful in optimizing conditions for the Biolog assay.

Comparison of the results of Biolog assay with surfactant die-away tests for the 36 isolates (Fig. 3) showed that for each of the readily biodegradable surfactants (PLAS, AES and SLAS), three groups of organisms could be identified by visual inspection. First, large groups of organisms (25/36 for PLAS, 26/36 for AES and 31/36 for SLAS) are centred around the zero points of both axes (Biolog colour < 100 for PLAS and < 50 for AES and SLAS; die-away scores < 20%). These groups are evidently comprised of non-surfactant-degrading organisms. Based on these data, Biolog thresholds for surfactant-degrading bacteria were set at 100 for PLAS, 50 for AES and 50 for SLAS. Members of a second, smaller group have low Biolog scores (< 100 for PLAS and < 50 for AES and SLAS), but show significant (> 20%) loss of MBAS activity. These organisms are primary degraders of surfactant but are not Biolog-positive. The third group shows loss of MBAS (> 20%) and high values of Biolog colour (> 100 for PLAS and > 50 for AES and SLAS): for PLAS, three of the environmental isolates and four of the known degrading organisms were in this group, while for AES there were three environmental isolates and three known degraders, and for SLAS, no environmental isolates and three known degraders. Since all the Biolog-positive isolates for these three surfactant classes showed high loss of MBAS during the surfactant die-aways, we conclude that all Biolog-positive organisms are primary surfactant-degrading organisms. However, the reverse is not true, and not all primary surfactant-degrading organisms are Biolog-positive. Previously, it has tacitly been assumed that organisms which accomplished primary biodegradation of alkyl sulphate esters by liberation of a long-chain alcohol, would also achieve ultimate biodegradation because the alcohol would be readily metabolized (White & Russell, 1994). Clearly this is not necessarily the case. None of the organisms which failed to accomplish primary degradation was found to be Biolog-positive. We believe this to be an important aspect of the validation process, because it demonstrates that the Biolog assay did not give any false-positive results.

The more recalcitrant surfactant classes (PANS and LABS) showed slightly different patterns (Fig. 3). Three groups were seen for PANS. The first was comprised of non-degraders (Biolog colour < 50 and die-away scores < 10%). The second contained a single example, namely the LABS-degrading consortium, which showed high loss of MBAS but no Biolog colour. This shows that the consortium has good primary biodegradative activity towards PANS but shows no Biolog activity towards that surfactant. This is consistent with the observation that no member of the consortium was able to grow with PANS as sole carbon and energy source. The third group contained one organism which was both Biolog-positive and a primary surfactant degrader. This was the isolate obtained by enrichment culture on PANS. For LABS, only two groups were observed, namely the non-degrading organisms and the primary degrader/Biolog-positive LABS-degrading consortium. As with the less
recalcitrant surfactants, no false-positive results were seen with these more recalcitrant compounds.

Comparison of the Biolog assay with growth on surfactant (Fig. 4) showed that, with the exception of LABS, all Biolog-positive organisms were capable of growth on the corresponding surfactant as sole carbon and energy source, i.e. they were capable of ultimate biodegradation of the surfactant. The fact that no individual isolate was able to grow on NANSA HS80/S matches the observations of several authors including Jimenez et al. (1991), Sigoillot & Nguyen (1992) and Terzic et al. (1992), all of whom found that a consortium was necessary to mineralize LABS. For the sulphated surfactants (PLAS, AES, SLAS), some organisms were capable of growth on surfactant as sole carbon and energy source but did not give Biolog-positive results. In view of the fact that the ability to grow on and mineralize surfactant should give rise to an increase in cell respiration and thus give a positive Biolog assay for that organism, the observation of such false-negatives is puzzling. The explanation may lie in the method used to grow the cells for the Biolog assay: although the growth medium M was supplemented with low concentrations of each surfactant (0.5 mM in total), this may have been insufficient to induce surfactant-degrading enzymes or to prevent the loss of plasmids which might encode for some degradative enzymes. Thus, the bacterial inoculum used in the Biolog assay may have been incapable of biodegrading the surfactant at a sufficient rate to give a positive Biolog result. In comparison, when the bacteria are inoculated in a medium containing the surfactant as the sole carbon and energy source, the ability to biodegrade the surfactant is necessarily maintained. To overcome this problem, each isolate would need to be grown individually on each surfactant, as indeed was done in this study with the known surfactant-degrading organisms. This should prevent loss of degradative capacity but would increase the workload of the assay by a factor of five. When dealing with large numbers of environmental isolates, such an increase in the time required is unhelpful. Moreover, in natural aquatic systems alternative carbon sources are likely to accompany surfactants. Consequently the Biolog protocol in which cells grow in the combined presence of surfactant and other carbon sources, is likely to reflect more closely the numbers of degraders that are active in the environment.

The adaptation and development of the Biolog assay has facilitated investigation of the pattern of anionic surfactant biodegradation in 30 environmental bacterial isolates from a polluted riverine site. That fraction of the epilithic isolates which gave a positive reaction in the Biolog assay was about 10% for PLAS and AES, and zero for SLAS, PANS and LABS. The value for PLAS is in close agreement with previous studies of polluted rivers in South Wales (Anderson et al., 1988; White et al., 1985). The absence of any SLAS Biolog-positive isolates was surprising, particularly since five isolates were capable of growth on SLAS and thus were Biolog false-negatives. This aside, the fractions of degrading organisms appears to reflect the established order of recalcitrance of these surfactant classes (Swisher, 1987). Thus, sulphate esters were generally the most readily degradable and had the highest fraction of Biolog-positive isolates, while the sulphonates were more recalcitrant and had the lowest fraction of Biolog-positive results. The SDS-degrading isolate, *Pseudomonas* C12B, gave positive results for all the classes of sulphated surfactants, a versatility which matches the known battery of sulphatase activity in this organism (Bartholomew et al., 1978; Cloves et al., 1980; Shaw et al., 1980; Bateman et al., 1986; Hales et al., 1986). The LABS-degrading consortium appears to be metabolically diverse and is capable of biodegrading all the sulphated and sulphonated surfactants used during this study.

The basic Biolog methodology as modified in this study to investigate anionic surfactant biodegradation, has many other potential applications. For example, it can be used to investigate the biodegradation specificities of pure isolates towards homologous series of compounds. It can also be used to assay whole environmental samples such as those obtained from resuspended biofilms. The use of the LABS-degrading consortia in this study and the use of environmental samples by Garland & Mills (1991) demonstrates that the Biolog assay can be used to test not only pure isolates but also whole bacterial communities. The direct testing of such intact communities without an intermediate growth step in the laboratory (which introduces an artificial selection) will help provide further insight into the microbial ecology of natural environments.

Little research utilizing the Biolog MT plate has been published, and the manufacturer's bibliography, dated May 1994, contains a total of six such papers. Previous research utilizing this methodology has studied the biodegradation of a variety of organic compounds (vide infra); those researchers concentrated on the results obtained using Biolog and did not report any validation of the method against more traditional methods. In contrast, the work presented here addresses this problem with respect to the use of Biolog MT plates with anionic surfactants and proves that it is a valuable tool in investigating the ecology, microbiology and biochemistry of surfactant biodegradation.

ACKNOWLEDGEMENTS

We wish to thank Albright and Wilson for their donations of surfactant samples and Dr M. J. E. Hewins for NMR analysis of surfactant samples. This research was supported by a Natural Environment Research Council grant (GR3/7858).
