By using MudJ (Kan, lac)-directed operon fusion technology, mutants of Salmonella typhi whose gene expression is induced under anaerobic growth conditions were isolated. Characterization of their phenotypes and regulatory properties revealed that two of the mutants were unable to use nitrate as a terminal electron acceptor in the absence of oxygen, suggesting that they were defective in nitrate reductase activity. Anaerobic induction of these fusions did not further increase in response to nitrate. Strains carrying an additional mutation in oxaR were constructed. They showed a lower level of \( \beta \)-galactosidase expression both aerobically and anaerobically; however, the ratios of anaerobic induction remained unaltered. These MudJ insertions mapped to the 17–19 min region of the chromosome. Based upon their phenotypes and mapping, one of the mutants probably possessed a modC (chlD)::MudJ insertion and the other a moaA (chla)::MudJ insertion. A third mutant was unable to use either nitrate or fumarate as a terminal electron acceptor. All three mutants showed a reduced ability to enter into and proliferate within HEp-2 epithelial cells. The oxaR mutation enhanced entry and proliferation of both the wild-type cells and the three mutants. Taken together, these results suggest that anaerobic respiration plays a role in S. typhi invasiveness.

Keywords: Salmonella typhi, anaerobiosis, nitrate respiration, invasiveness

INTRODUCTION

Salmonella typhi, the causal agent of typhoid fever, is a specific human pathogen. Fundamental for S. typhi infectivity is its capacity to cross the mucosa of the distal ileum, as well as to survive and multiply within macrophages (Di Rita & Mekalanos, 1989; Finlay & Falkow, 1989; Grosman & Saier, 1990; Falkow et al., 1992). To persist and establish a successful infection, S. typhi must be able to adapt to the fluctuating environmental conditions encountered within the human host. There is a growing body of evidence showing that bacterial pathogens are constantly sensing their environment and adjusting to it by regulating the expression of several genes and operons. This response often involves changes in the expression of genes encoding virulence factors (Miller et al., 1989; Dorman, 1991; Falkow et al., 1992; Mekalanos, 1992).

One of the conditions encountered by S. typhi during invasion of the intestinal epithelium, as well as in tissues during systemic infection of the human host, is low oxygen availability (Lee & Falkow, 1990), for which enteric bacteria have developed adaptive responses. Facultative anaerobes, such as Escherichia coli and Salmonella typhimurium, can grow under aerobic or anaerobic conditions, deriving energy from a variety of respiratory or fermentative processes. Aerobically, oxygen serves as a terminal electron acceptor. Anaerobically, alternative respiratory chain acceptors, such as nitrate, nitrite, fumarate or dimethylsulphoxide, can be utilized (Poole & Ingledew, 1987; Lin & Kuritzkes, 1987). Both global and specific regulatory systems have been implicated in the regulation of anaerobic gene expression, to ensure that the most energetically favourable metabolic process is adopted (Spiro & Guest, 1991; Stewart, 1993; Guest, 1995).

There is evidence that oxygen availability may be an environmental signal controlling Salmonella virulence. It has been shown that anaerobiosis induces the invasion phenotype in S. typhimurium (Ernst et al., 1990; Schiemann & Shoppe, 1991; Jones & Falkow, 1994) as well as in S. choleraesuis and S. typhi (Lee & Falkow,
I. CONTRERAS AND OTHERS

1990; Tartera & Metcalf, 1993; Tartera et al., 1993). Two oxygen-regulated invasion loci, hil (Lee et al., 1992) and orgA (Jones & Falkow, 1994), required for S. typhimurium internalization into epithelial cells have been identified. However, their specific functions are unknown.

In a previous study we showed that the ability of S. typhi strain Ty2 to enter into and proliferate within HEp-2 epithelial cells was enhanced in anaerobically grown bacteria (Contreras et al., 1995a). To identify anaerobically induced genes required for the invasion and proliferation of S. typhi strain Ty2 in cultured cells, we isolated several MudJ operon fusions in oxygen-regulated genes and characterized them as to their abilities to enter into and multiply within epithelial and phagocytic cell lines of human origin (Contreras et al., 1995a). In the present work we further characterize three of these anaerobically induced fusions. These mutants are defective in the nitrate respiratory system required for S. typhi strain Ty2 at an m.o.i of 0.01 p.f.u. per bacterium. After incubation for 20 min to allow phage adsorption followed by another 40 min with shaking in the presence of 15 mM EDTA, transductants were plated on LB agar plates containing kanamycin. After incubation for 18 h at 37 °C, colonies were replicated on LB agar plates containing kanamycin and the chromogenic substrate for β-galactosidase, X-Gal (Miller, 1972). Duplicate plates were incubated aerobically and anaerobically. After anaerobic growth the plates were placed at 4 °C under aerobic conditions for 30 min to allow oxidation of indole produced by hydrolysis of X-Gal during growth. Colonies that appeared to produce more β-galactosidase under anaerobic conditions (dark blue on X-Gal) were selected for further studies. β-Galactosidase assays were performed in vitro as described by Miller (1972) on cultures grown under aerobic and anaerobic conditions to mid-exponential phase (OD600 = 0.2).

Clones regulated by oxygen availability were characterized as follows. The outer-membrane-enriched fraction was obtained as described by Contreras et al. (1995b) and proteins were analyzed by SDS-PAGE in 12.5% polyacrylamide slabs using the procedure of Laemmli (1970) as modified by Lobos & Mora (1991). Motility was examined by stabbing into semi-solid MIO medium (Difco).

Genetic techniques. Transductions were performed by using the high-transducing phage P22 HInt as described by Maloy (1990). The approximate chromosomal location of MudJ insertions was determined by the method of Benson & Goldman (1992). This mapping technique is based on a set of S. typhimurium strains carrying locked-in Mud-P22 prophages in different locations on their chromosome. To use this technique, the MudJ insertions were first moved to S. typhimurium strain MST1 by transformation with linear fragments of chromosomal DNA from the mutants. The method used was based on the one described by Russell et al. (1989) and modified by N. Bossi & L. Bossi (Centre de Génétique Moléculaire, CNRS, France; personal communication). Electroporation was performed as described by O’Callaghan & Charbit (1990).

Invasion and intracellular proliferation assays. To measure invasion and intracellular proliferation of S. typhi strain Ty2 and its derivatives with oxygen-regulated operon fusions in HEp-2 epithelial cells, an in vitro assay based on the method described by Lissner et al. (1983) was used. Approximately 5 x 10⁶ c.f.u. (100 µl) bacteria grown to mid-exponential phase were centrifuged, resuspended in 100 µl DME/5% FBS (Dulbecco’s modified Eagle medium supplemented with 10%, v/v, foetal bovine serum) and added to six wells containing cell monolayers at a ratio of 10:1 bacteria per cell. After incubation for 1 h in a 10% CO₂/90% air atmosphere to allow for bacterial entry into the cells, monolayers were washed twice with phosphate-buffered saline (PBS: NaCl, 0.8% w/v; KCl, 0.02%, w/v; Na₂HPO₄, 2H₂O, 0.13%, w/v; K₂HPO₄, 0.02%, w/v) and then 100 µl DME/5% FBS containing gentamicin (250 µg ml⁻¹) was added to each well and the plates were incubated for 2 h to kill any remaining extracellular bacteria. The medium was removed and the cells were washed twice with PBS. Fresh medium containing gentamicin (25 µg ml⁻¹) was added and cells from three wells were lysed with sodium deoxycholate (0.5%, w/v, in PBS). The number of intracellular bacteria (c.f.u. at tₜₐₜ) was determined by plating onto LB agar plates. The remaining three wells were incubated for 20 h to allow intracellular proliferation. The monolayers were then lysed and bacteria were counted (c.f.u. at tₜₐₜ). Quantitative invasion assay results were calculated as follows:
Values are expressed as β-galactosidase activity in Miller units (Miller, 1972). Cultures were grown under anaerobic conditions in LB or E medium with the supplements indicated. Data are from one representative experiment. Each experiment was repeated at least three times.

**RESULTS**

Fusions in genes involved in anaerobic respiration are required for *S. typhi* proliferation within epithelial cells

From a collection of 12346 random MudJ insertion mutants of *S. typhi* we had previously selected 25 mutants which were shown, by β-galactosidase measurements *in vitro*, to contain fusions in genes whose expression was induced during anaerobic growth (Contreras et al., 1995a). Three of the mutants, which were found to be impaired in invasiveness and proliferation within HEp-2 cells (Table 1), are further characterized in this work.

We confirmed that the impaired abilities to invade epithelial cells exhibited by the mutants were linked to

Mutants defective in anaerobic respiration are chlorate resistant

To investigate whether the fusions in mutants JJ3, NN19 and DD46 occurred in genes involved in anaerobic metabolism, the effect of sugars and alternative electron acceptors was studied. When the mutants were grown in E medium supplemented with glucose, generation times were similar to those in complex media (data not shown). The β-galactosidase levels of the mutants were similar under each of the anaerobic growth conditions tested (Table 2). Mutants JJ3 and NN19 were unable to grow in E medium supplemented with glycerol and nitrate. Because *S. typhi* cannot ferment glycerol anaerobically, growth in this medium must be sustained from nitrate respiration. These results suggest that these mutants lack nitrate reductase activity. Mutant DD46 did not grow in E medium supplemented with glycerol and either nitrate or fumarate as the terminal electron acceptor (Table 2). In addition, we observed that the three mutants, as well as the wild-type strain, were unable to grow in E medium supplemented with glycerol and dimethylsulphoxide, suggesting that *S. typhi*, in contrast to *S. typhimurium* and *E. coli*, lacks dimethylsulphoxide reductase activity.

1988). As shown in Table 3, the mutants were 10²–10⁸ times more resistant to chlorate than the parental strain.

Lack of nitrate reductase activity leading to chlorate resistance is often caused by mutations in chl (mol) loci, which are implicated in the synthesis, insertion or processing of molybdenum cofactor (Stewart & MacGregor, 1982; Stewart, 1988). Therefore, we tested the effect of molybdenum on the growth of the mutants on glycerol and nitrate medium. Two of the mutants were unaffected by molybdenum, but growth of mutant NN19 was restored when cultured in E medium with glycerol and nitrate supplemented with sodium molybdate, the doubling time being similar to that of the parental strain (Fig. 1). This result suggests that the mutation in mutant NN19 could be in the modC (chlD) gene, involved in the active transport of molybdenum (Johann & Hinton, 1987; Miller et al., 1987; Scott & Amy, 1989). In E. coli, mod mutants are unique in that the effect of the mutation can be suppressed by an increase in the molybdate concentration in the medium (Glaser & DeMoss, 1971; Sperl & DeMoss, 1975; Stewart & MacGregor, 1982).

MudJ insertions map to 17–19 min and 67–69 min regions of S. typhimurium chromosome

It has been previously reported that mutations in the E. coli nitrate reductase structural genes (the chlC locus or narG operon) do not result in a chlorate-resistant phenotype (Glaser & DeMoss, 1971; Stewart & MacGregor, 1982). Accordingly, when we transduced each mutant strain with a P22 lysate propagated on S. typhimurium strain TT10269 (chlC::Tn10) no replacement of the Kan' phenotype with a Tet' phenotype was found, indicating that MudJ fusions were not within the chlC locus.

The approximate chromosomal location of MudJ insertions was determined with the aid of strains carrying Mud-P22 insertions at defined positions on the S. typhimurium chromosome. The MudJ insertions mapped to the 17–19 min region (mutants NN19 and JJ3) and 67–69 min region (mutant DD46) of the S. typhimurium chromosome.

The oxrA mutation affects expression of β-galactosidase from operon fusions

The S. typhimurium oxrA (fnr) gene product is a positive regulator of the anaerobically inducible genes, similar to the E. coli Fnr protein (Strauch et al., 1985). To determine the effect of an oxrA mutation on the fusions studied in this work, we transduced an oxrA2::Tn10 insertion from S. typhimurium strain MST2970 into each mutant. In the case of mutants JJ3 and NN19, the oxrA mutation reduced expression of β-galactosidase under both aerobic and anaerobic conditions. However, the anaerobic induction ratio remained almost unaffected (Table 4), suggesting that other regulatory gene(s) are functional in S. typhi. The oxrA mutation clearly affected expression of β-galactosidase from mutant DD46, reducing the ratio of anaerobic induction to less than twofold (Table 4). The oxrA mutation had no additional effect on expression of the three fusions when the mutants were grown anaerobically in nitrate-supplemented media; the β-galactosidase levels remained similar to those measured in media without nitrate under anaerobic conditions (Table 4).

To determine the regulatory effect of the oxrA gene on the expression of the chlC gene in S. typhi, a strain carrying an oxrA mutation and a chlC::MudA fusion was constructed. As shown in Table 4, the oxrA mutation reduced expression of β-galactosidase under both aerobic and anaerobic conditions. However, the anaerobic induction ratio was enhanced about twofold (Table 4).

The oxrA mutation suppresses the invasion/proliferation defect of the anaerobically induced mutants

To evaluate the functional consequences of the oxrA mutation, we assayed the mutants ability to enter into and proliferate within HEp-2 cells. Unexpectedly, the oxrA mutation restored the capacity of the anaerobically induced mutants to invade epithelial cells (Table 5). Furthermore, our results suggest a potentiation of the invasiveness of the mutants. This effect was also observed with an oxrA derivative of the wild-type strain. These results indicate that the oxrA gene enhances both invasion and proliferation of S. typhi, and that these effects are independent of the three mutations characterized in this study. The reasons for the effect of the oxrA gene are currently being investigated.

Anaerobic growth induces synthesis of membrane proteins

It has been reported that chlorate-resistant mutants of E. coli have a complex phenotype (Graham et al., 1980). The pleiotropic nature of such mutants has been proposed to result from alterations in the structure of the membrane (MacGregor & Schnaitman, 1971).

Electrophoretic analysis of membrane fractions showed that anaerobic growth strongly induced the synthesis of two proteins with apparent molecular masses of 41 and 28·5 kDa in the wild-type strain. On the other hand, a protein of 39·7 kDa was repressed (Fig. 2, lane C). The addition of nitrate to the growth medium caused the induction of a 134·8 kDa protein (Fig. 2, lane D). The latter protein band appeared in the membrane fraction of mutants DD46 and JJ3 when grown anaerobically, both in the absence and in the presence of nitrate (Fig. 2, lanes I, J, O and P), but it was not synthesized by mutant NN19 under any growth condition tested (Fig. 2, lanes K–M). In all the mutants a protein band with an apparent molecular mass of 118·5 kDa was visible in the membrane fraction of anaerobically grown cells (Fig. 2, lanes I, J, L, M, O and P).

As shown in Fig. 2, another chlorate-resistant mutant (MM46) isolated by us also produced the 134·8 and 118·5 kDa proteins when grown under anaerobic conditions (Fig. 2, lanes F and G). This mutant was not characterized further in this work because, in contrast to mutants DD46, NN19 and JJ3, it had a rough lipopolysaccharide (Contreras et al., 1995a), a fact that does not allow the use of phage P22 for transduction experiments.

Growth in semi-solid MIO medium and observation by light microscopy showed that under aerobic conditions the three mutants were motile. However, in contrast to the parental strain, all three mutants were non-motile.

when grown in nitrate-supplemented LB under anaerobic conditions. Mutant NN19 was unique in that this defect was suppressed by the addition of sodium molybdate to the culture medium. By transmission electron microscopy it was observed that the non-motile bacteria were flagellated (data not shown). We believe that this result could be explained by the lack of nitrate reductase activity as this respiratory enzyme participates in the generation of proton-motive force that drives flagellar movement (Morpeth & Boxer, 1985; Gennis & Stewart, 1996).

**DISCUSSION**

As part of our interest in the identification of genes that allow *S. typhi* to survive and multiply within the human host, we have isolated a collection of anaerobically induced lacZ operon fusions and characterized them with respect to their abilities to enter into and proliferate within HEp-2 epithelial cells (Contreras *et al.*, 1995a). In the present work we have further characterized three of these anaerobically induced operon fusions whose ability to proliferate within HEp-2 cells is considerably diminished compared to the parental strain. All three mutants were unable to grow anaerobically in media containing a non-fermentable substrate (glycerol) with nitrate as the terminal electron acceptor, suggesting that they lack nitrate reductase activity. By phage P22 transduction of a *chlC::Tn10* insertion from *S. typhimurium* into these mutants, we demonstrated that the MudJ insertions are not located in the *chlC* (*nar*) locus.

The three mutant strains showed a chlorate-resistant phenotype. Other studies have shown that virtually all chlorate-resistant mutants of *E. coli* have alterations in the synthesis or assembly of molybdenum cofactor. Five *mol* (formerly *chl*) loci have been identified; the *moaA* (*chlA*) and *moe* (*chlE*) gene products are involved in synthesis of molybdopterin (Pitterle & Rajagopalan, 1989), the *mod* (*chlD*) gene product is involved in the active transport of molybdenum (Johann & Hinton, 1987; Miller *et al.*, 1987; Scott & Amy, 1989), the *mob* (*chlB*) gene product is required for molybdenum processing (Johnson *et al.*, 1991) and the *mog* (*chlG*) gene product has an unknown function (Garzon *et al.*, 1992; Rajagopalan & Johnson, 1992). Growth of fusion strain NN19 was restored to wild-type levels in medium supplemented with molybdate, indicating that this is probably a *mod* mutant. The genetic mapping results support this conclusion, namely, the MudJ insertion in mutant NN19 maps in the 17–19 min region of the chromosome and the *S. typhimurium chlD* (*modC*) gene has been mapped at the 18.3 min (Sanderson *et al.*, 1995).

Characterization of *oxrA* derivatives of these mutants indicates that anaerobic induction of fusions NN19 and JJ3 is independent of the *oxrA* gene, suggesting alternative regulation of these loci. In *S. typhimurium*, in addition to the *oxrA* gene (similar to the *fnr* gene of *E. coli*) and the *oxrB* gene, which are essential for the anaerobic induction of several respiratory enzymes, two other regulatory genes, *oxrC* and *tppR*, have been described (Jamieson & Higgins, 1986). The *oxrA* mutation, on the other hand, reduced the anaerobic induction of mutant DD46 fusion expression. This result, together with the observation that this mutant is unable to utilize both nitrate and fumarate as terminal electron acceptors anaerobically, suggests that the MudJ insertion is probably affecting a gene which is regulated by the *oxrA* gene and is involved in the anaerobic induction of both nitrate and fumarate reductases in *S. typhi*.

Examination of membrane proteins by SDS-PAGE
showed that the addition of nitrate to wild-type *S. typhi* growing anaerobically in complex medium caused increased synthesis of a protein of approximately 140 kDa. This protein was present in membrane fractions of all the mutants in the absence of nitrate, with the exception of mutant NN19. It is tempting to speculate that this protein might correspond to the alpha-subunit of nitrate reductase, which in *E. coli* has a molecular mass of 142 kDa (Stewart & MacGregor, 1982). The fact that mutant NN19 does not synthesize this protein supports this notion. In *chld* mutants of *E. coli*, the band corresponding to nitrate reductase is not found in SDS-PAGE gels of membrane fractions (MacGregor & Schnaitman, 1971). Mutant strain J35 might be a *chlA*-type mutant in which the nitrate reductase is present in the membrane fraction but does not function (MacGregor & Schnaitman, 1971). The approximate map position within the 17–19 min region, as well as its nitrate-independent expression, is in accordance with properties reported in *chlA* mutants of other enterobacteria: *S. typhimurium* *chlA* (moaA) gene maps at 19 min on the bacterial chromosome (Sanderson et al., 1995) and transposon insertions in the *chlA* gene result in constitutive *nar-lacZ* expression (Pascal et al., 1982). Finally, mutant DD46 might be a *chle*-type mutant, which in *E. coli* barely grows in a medium containing glycerol and fumarate (Pascal & Chippaux, 1982).

Although oxygen regulation of protein synthesis has been extensively studied in other facultative anaerobes, such as *E. coli* and *S. typhimurium*, very little is known about the effects of anaerobiosis on gene expression in *S. typhi*, due in part to the lack of adequate tools for genetic analysis in this human pathogen. In the present work we have shown that anaerobically induced genes which are involved in nitrate respiration are required for *S. typhi* invasiveness. The role of these genes in the invasion process may be an indirect one, for example, in providing the most energetically favourable metabolic processes for bacterial survival and proliferation. Alternatively, genes involved in anaerobic respiration may be coordinately regulated with genes encoding invasive processes. Our results support recent findings, using *in vivo* expression technology, which show that mutations in several *S. typhimurium* genes involved in metabolic pathways result in reduced virulence in mice (Mahan et al., 1993; Moors & Portnoy, 1995). This is in agreement with an expansive view of virulence determinants which includes not only those factors that cause disease, but also those functions that contribute to bacterial survival and multiplication in the host (Mekalanos, 1992; Groisman & Saier, 1990).

**ACKNOWLEDGEMENTS**

We gratefully thank S. Maloy and J. Roth for providing bacterial strains. This work was supported by grants FONDECYT 1960864 and 1960255 and by a grant from Dirección de Investigación y Postgrado Universidad Católica de Chile (DIPUC). The mapping experiments were performed at the laboratory of Lionello & Nara Bossi (Centre de Génétique Moléculaire, CNRS, France), whose help and advice are gratefully acknowledged. The work of C.S.T. and G.C.M. at L. Bossi’s laboratory was supported by the ECOS-CONICET Program.
