Periplasmic maltose- and glucose-binding protein activities in cell-free extracts of *Thermotoga maritima*

Dhaval Nanavati, Kenneth M. Noll and Antonio H. Romano

In this study, high-affinity maltose- and glucose-binding activities in cell-free extracts of *Thermotoga maritima* were detected; these activities were distinct and specific. At the gross level, the expression of binding-protein activities was repressed by growth of *T. maritima* in the presence of the cognate sugar. Growth of the organism in the presence of maltose reduced maltose-binding activity but not glucose-binding activity, while growth in the presence of glucose reduced glucose-binding activity but not maltose-binding activity. In competition assays, these binding activities showed distinct patterns of substrate specificity: whereas the maltose-binding activity showed specificity for α-linked glucosides, the glucose-binding activity showed a broader specificity. All maltose- and glucose-binding activity was found in the supernatant retrieved following centrifugation (100,000 g) of the cell-free extracts prepared by French-pressure-cell treatment; no activity was found in an octyl-glucoside-treated extract of the membrane fraction. The maltose-binding-protein activity was recovered from the periplasmic fraction by selective release of the periplasmic contents of *T. maritima* cells using a newly developed freeze–thaw procedure. Annotation of the complete genome sequence of *T. maritima* suggests that there may be at least two maltose-binding proteins, MalE1 and MalE2, encoded in the genome. The maltose-binding activity corresponded to a protein of 43 kDa, which was consistent in size with either of the putative proteins. These data demonstrate that the hyperthermophilic bacterium *Thermotoga maritima* possesses separate maltose- and glucose-binding-protein activities that are freely soluble in its periplasm, in contrast to the membrane-bound sugar-binding proteins found in archaeal hyperthermophiles.

**Keywords**: hyperthermophile, sugar transport, ABC transporters, transporter evolution

**INTRODUCTION**

The suite of substrate transporters expressed by a cell dictates how readily an organism can use available nutrients in its environment. Consequently, transporters are important elements in the evolution of cellular metabolism and may dictate the competitive success of an organism in a given ecosystem. It is not surprising that among sequenced genomes transporters comprise a relatively large fraction of the coding capacity of these genomes (Paulsen *et al.*, 2000). Insights into the evolution of this important process can be gained by examining transporter functions among organisms that span the phylogenetic spectrum. Thus, we report here an examination of sugar-binding activities by the hyperthermophilic bacterium *Thermotoga maritima*.

Transporters can be classified into five groups based upon how energy is expended by an organism to effect concentrative uptake of substrates (Albers *et al.*, 2001). Two of these groups, the secondary transporters and the ATP-linked primary transporters, are ubiquitous among sequenced prokaryotic genomes (Paulsen *et al.*, 2000), suggesting that they were among the first transport systems to evolve. Secondary transporters use electrochemical energy stored in transmembrane ion gradients to drive solute translocation. Primary transporters...
use the energy of ATP hydrolysis to take up solutes and are called ATP-binding cassette (ABC) transporters. ABC transporters utilize periplasmic, high-affinity binding proteins to bring the substrate to the transmembrane components, which effect transport driven by hydrolysis of ATP catalysed by associated cytoplasmic ATP-binding proteins. Substrate-binding proteins differ among microorganisms, that in some are soluble in the periplasm while others, particularly among Gram-positive organisms, are tethered to the cell membrane (Jones et al., 2000; Paulsen, 1999). Recently, membrane-associated sugar-binding proteins were found in the archaeal species \textit{Thermococcus litoralis}, \textit{Pyrococcus furiosus} and \textit{Sulfolobus solfataricus} (Elferink et al., 2001; Koning et al., 2001a, b; Xavier et al., 1996). Given this distribution of ABC transporters, it is of interest to examine their distribution and function among representatives of evolutionarily important bacteria such as \textit{T. maritima}. On the basis of comparisons among 16S rRNA gene sequences, the order \textit{Thermotogales} represents a bacterial lineage that may resemble the earliest ancestors of the \textit{Bacteria} (Fitz-Gibbon & House, 1999; Pace, 1997). However, other measures of the evolution of protein-encoding sequences place \textit{T. maritima} and its related species higher in the bacterial lineage (Brochier & Philippe, 2002; Brown & Doolittle, 1997; Gupta, 1998; Klenk et al., 1999). The precise placement of this lineage notwithstanding, the order \textit{Thermotogales} clearly represents an evolutionarily and physiologically important group of organisms. Evidence suggests that this lineage has inherited DNA from archaea through lateral gene transfer (Nelson et al., 1999; Nesbo et al., 2001) and that some of these inherited genes encode putative transporters (Nelson et al., 2001). Thus, we set out to examine sugar transporters in \textit{T. maritima}, to better understand the constraints on such genetic exchanges and what impact they have had on the evolution of this organism.

We have previously shown that \textit{Thermotoga neapolitana}, a close relative of \textit{T. maritima}, does not have phosphoenolpyruvate:sugar phosphotransferase (PTS) transporters for glucose, fructose, galactose or lactose. Likewise, others have shown that the genome sequence of \textit{T. maritima} has no ORFs identifiable as PTS-encoding genes (Galperin et al., 1996, 1997; Nelson et al., 1999). Since the annotation of the \textit{T. maritima} genome sequence has suggested several ABC-type transporters may be encoded there, we set out to measure periplasmic sugar-binding activities in this organism. Here, we describe the first description of a method to selectively release the periplasmic contents of \textit{T. maritima}, a method that may be used to examine the periplasmic functions of this organism. We used this method to demonstrate that \textit{T. maritima} has both maltose- and glucose-binding activities and that the proteins responsible for these activities are located in its periplasm as soluble proteins. Furthermore, we have shown that the expression of these binding activities by \textit{T. maritima} is differentially regulated in response to the growth substrate used.

METHODS

Organism and growth conditions. \textit{T. maritima} MSB8$^7$ (DSM 31095) was obtained from the Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig, Germany. Cells were grown on a modified basal defined medium (Childers et al., 1992) that contained (l$^{-1}$) 20 g NaCl, 4.8 g HEPES, 0.5 g cysteine, 0.25 g NH4Cl, 0.05 g CaCl$_2$, 0.05 g KH$_2$PO$_4$, 2 g KCl, 0.1 g MgSO$_4$, 2.5 g Na$_2$CO$_3$, 0.1 g FeSO$_4$7H$_2$O and 1 ml of a vitamin solution containing (l$^{-1}$) 10 mg pyridoxine/HCl, 5 mg calcium pantothenate, 5 mg nicotinic acid, 5 mg riboflavin, 5 mg thiamin/HCl, 5 mg thiodic acid, 2 mg biotin, 2 mg folic acid and 0.1 mg cyanocobalamin. The medium was dispensed into serum bottles and degassed by heating in a steam cabinet until the resazurin indicator was colourless. The bottles were closed with butyl-rubber stoppers with aluminium crimp seals and flushed with oxygen-free nitrogen for 10 min before sterilization by autoclaving at 121 °C for 30 min. Sugars used as the carbon and energy source were sterilized separately by filtration of anoxic solutions before addition to the medium at a final concentration of 5 g l$^{-1}$. When yeast extract was used in the medium instead of sugars it was added to the medium, before autoclaving, at a concentration of 1 g l$^{-1}$.

Cells were grown at 77 °C under strictly anaerobic conditions. Typically, 15 ml of an overnight culture were transferred to 300 ml fresh medium and grown to late-exponential phase (24 h for glucose, 12 h for maltose). For harvesting of the cells, cultures were cooled to 4 °C overnight, centrifuged at 4 °C at 6000 g for 20 min, resuspended in a wash buffer (50 mM KCl, 2 mM MgSO$_4$, 40 mM KH$_2$PO$_4$, pH 7.0) and then centrifuged again at 6000 g. The resulting cell pellet was stored at −20 °C for further processing.

Preparation of cell extracts. Cell extracts of \textit{T. maritima} were prepared by two methods. (A) Cells harvested and washed as above were resuspended in 7–10 ml of 50 mM Tris/HCl buffer (pH 7.5) containing 1 mM MgSO$_4$ and 1 mM PMSF, then ruptured by one passage through a French pressure cell (Aminco) at 20000 p.s.i. (137.8 MPa). Cell debris and membrane fragments were separated by centrifugation at 100000 g for 1 h at 4 °C. The supernatant was saved as the ‘soluble fraction’. To extract membrane proteins, the pellet was washed with 5 ml of 50 mM Tris/HCl (pH 7.5) containing 1 mM MgSO$_4$, centrifuged again at 100000 g, then extracted with 5 ml of 1% octyl glucoside in 50 mM Tris/HCl (pH 7.5) by gentle stirring overnight at 5 °C. (B) Where indicated, cells were disrupted by suspension in 0.2% Triton X-100 in 50 mM Tris/HCl (pH 7.5) containing 1 mM PMSF. The resulting extract was clarified by centrifugation at 10000 g. Protein content in all extracts was determined by the method of Bradford (1976) (Sambrook et al., 1989).

Fractionation of cells to release periplasmic and cytoplasmic proteins. A freeze–thaw procedure was used to selectively release periplasmic proteins from \textit{T. maritima}. Frozen cell pellets that had been maintained at −20 °C for 48 h were suspended in 50 mM MgCl$_2$ in 50 mM Tris/HCl (pH 7.5) at a cell density of 140 mg wet wt ml$^{-1}$ and stirred for 30 min at room temperature. The suspension was centrifuged at 8000 g for 10 min, then washed with distilled water by stirring for 1 h at room temperature and centrifuged again. The pelleted cells were then treated with 0.2% Triton X-100 in 50 mM Tris/HCl (pH 7.5). Maltose-binding activity and enolase activity were measured at each step.

Determination of maltose and glucose binding. The procedure of Richarme & Kepes (1983) was followed, whereby the sugar-binding protein–ligand interaction with ammonium
sulfate allows adsorption to cellulose ester filters. Glass test tubes (12 × 100 mm) containing 50 µl of the extract containing binding protein and 10 µl of water or another specified addition were pre-heated in a heating block at 55 °C (or other specified temperature) for 30 s, then 10 µl of 7 µM α-D-[U-14C]maltose (594 mCi mmol⁻¹, 2198 GBq mmol⁻¹; ICN) or α-D-[14C]glucose (210 mCi mmol⁻¹, 7.7 GBq mmol⁻¹; ICN) was added rapidly to the samples with a micropipette. After an additional 30 s (or other specified time) at 55 °C, 2 ml of ice-cold, saturated (NH₄)₂SO₄ in 50 mM Tris/HCl (pH 7.5) was added to the samples and the tubes were transferred to an ice bath for at least 10 min. The contents of the tubes were then filtered through Whatman cellulose nitrate membrane filters (25 mm, 0.45 µm porosity) and washed with an additional 2 ml of ice-cold, saturated (NH₄)₂SO₄ in buffer. The filters were then placed in scintillation fluid (Optifluor; Packard) for counting in a Beckman LS 3801 liquid scintillation spectrometer. Apparent binding constants of approximately 0.3 µM were determined for both glucose and maltose using the cell extracts of T. maritima. As described above, routine binding assays used a saturating concentration of these sugars (over threefold excess).

**Enolase assay.** Enolase (EC 4.2.1.11) activity was measured at 77 °C by monitoring the formation of phosphoenolpyruvate (PEP) spectrophotometrically at 240 nm. The extinction coefficient of PEP was determined by us to be 1.4 mM⁻¹ cm⁻¹ in 100 mM Tris/HCl (pH 8.0). The assay mixture contained 100 mM Tris/HCl (pH 8.0), 5 mM 2-phosphoglycerate, 2 mM MgSO₄ and 50–100 µl of cell extract in a final volume of 1 ml.

**SDS-PAGE of maltose-binding protein and detection of binding activity in a non-denaturing gel.** Periplasmic protein fractions prepared by the freeze–thaw procedure described above were concentrated by ultrafiltration (10000 Da cut-off). Fifty microlitres of the periplasmic extract was incubated with 10 µl of 7 µM α-D-[U-14C]maltose (594 mCi mmol⁻¹, 2198 GBq mmol⁻¹) and 10 µl of water at 50 °C for 30 s to allow binding, then an equal volume of 2× loading dye was added to the assay. An aliquot of this mixture (120 µl) was loaded onto a non-denaturing 10% polyacrylamide gel, prepared as described by Sambrook et al. (1989). Adjacent lanes were loaded with 50 µl of the periplasmic extract. After electrophoresis for 12 h at room temperature, the gel was washed with distilled water to remove any unbound radioactive sugar. The lane loaded with the radioactive binding mixture was cut into 0.25 or 0.5 cm strips, which were individually transferred to scintillation fluid for determination of radioactivity. One adjacent lane of the gel was stained with 0.1% Coomassie blue and destained with an acetic acid/water/methanol mixture (1:3:6) to visualize the protein bands. The other adjacent lane was cut at the location corresponding to radioactivity detected in the band loaded with the binding mixture, and the excised piece of gel was extracted with 0.1 ml of 0.5% SDS in 25 mM Tris/HCl for 24 h at 4 °C. An aliquot of this eluate (50 µl) was loaded onto a 12% polyacrylamide denaturing gel and subjected to electrophoresis.

**RESULTS AND DISCUSSION**

**Maltose and glucose binding in cell-free extracts of T. maritima**

Extracts of cells grown on maltose or glucose and disrupted by French-pressure-cell treatment (method A) showed binding of both [14C]maltose and [14C]glucose. Separation of the soluble and particulate fractions of the French-pressure-cell extracts by ultracentrifugation at 100000 g and subsequent extraction of the particulate fraction by octyl glucoside showed that maltose- and glucose-binding activities were predominantly associated with the soluble fraction – [14C]maltose and [14C]glucose were bound by the soluble fraction at 53 and 20 nmol sugar (mg protein)⁻¹, respectively, whereas they were bound by the membrane fraction at 4.1 nmol sugar (mg protein)⁻¹, respectively. This is in contrast to the maltose-binding protein of the hyperthermophilic archaeon T. litoralis, which has been shown to be membrane-associated (Xavier et al., 1996). It should be noted that cell extracts for [14C]maltose-binding experiments were prepared from glucose-grown cells while extracts used for [14C]glucose-binding experiments were prepared from maltose-grown cells. As noted below, binding activities were lowest in cells grown on the cognate sugar.

These maltose- and glucose-binding activities appear to be distinct, since the patterns of inhibition of isotopic sugar binding to protein by non-isotopic sugars indicated different patterns of specificity. A comparison of the sugar-binding specificities as determined by the inhibition of isotopic sugar binding is shown in Table 1. Maltose binding appeared to be strongly dependent on the α-glycosidic linkage, since the α-glycosides trehalose and methyl α-D-glucopyranoside significantly inhibited maltose binding while the β-galactosides cellobiose and lactose had little or no effect on this binding. The monosaccharides tested showed low inhibition of maltose binding, with α-D-glucose, the constituent monosaccharide of maltose, showing a greater effect than α-D-galactose. Glucose binding showed a broader specificity, with α- or β-linked disaccharides containing a glucose moiety all showing a degree of binding inhibition. α-D-Galactose, a β-D-glucose epimer, showed the least inhibition of glucose binding.

**Effect of temperature on maltose and glucose binding**

We examined the effect of temperature on maltose and glucose binding using Triton X-100 cell extracts. Binding of these sugars showed apparent optimal temperatures of 60 °C for maltose and 50 °C for glucose, though there was significant binding of both sugars at 0 °C (53 and 47% of the maximum for maltose and glucose, respectively). Sugar binding at 78 °C, the optimal growth temperature of T. maritima, was 79 and 72% of the maximum for maltose and glucose, respectively. The decrease in binding activity at higher temperatures might be due to the activation of proteases in the cell extracts. A purified recombinant maltose-binding protein from T. maritima expressed in Escherichia coli was thermally stable to over 105 °C (Wassenberg et al., 2000).

**Release of maltose-binding activity from the periplasm**

With the objective of further localizing the sugar-binding cellular constituent(s) of T. maritima, we set about developing a method to release the presumed binding

proteins from cells of this organism. Having found that the binding activity was not membrane-bound (see above), we investigated a number of osmotic-shock procedures that have been successful in releasing sugar-binding proteins from the periplasm of a number of Gram-negative bacteria. The procedure we found to be most useful for *T. maritima* was a freeze–thaw procedure involving extraction of frozen cells with 50 mM MgCl₂ in Tris/HCl (pH 7.5) (see Methods). The results of assays of [14C]maltose- and [14C]glucose-binding activities carried out on fractions obtained from this procedure are shown in Table 2. Enolase activity was also measured in each fraction to determine the levels of contamination with cytoplasmic enzymes within these fractions. The freeze–thaw/MgCl₂ buffer extraction combined with the subsequent distilled-water wash recovered more than 84% of the maltose- or glucose-binding activities and only 10–14% of the enolase activity. By comparison, the Triton X-100 extract of the residual cells contained 87–90% of the total enolase activity.

activity and only 11–17% of the total maltose-binding activity. Thus, the sugar-binding proteins are soluble in the periplasmic fraction of cells of *Thermotoga maritima*.

Effect of growth medium on maltose- and glucose-binding activity

Our intent was to grow *T. maritima* on a number of different carbon sources, including carbohydrates and other classes of compounds, so that we might observe patterns of induction or repression of binding-protein synthesis. However, growth of *T. maritima* is obligately dependent on the fermentation of sugars, and we were not able to grow the organism on such complex low-carbohydrate substrates as peptone or on fermentation intermediates such as pyruvate. The closest we could come to a complex organic substrate that supported growth of the organism was yeast extract, but this material contains significant amounts of the yeast storage disaccharide trehalose. Indeed, Xavier *et al.* (1996) found that trehalose was an inducer and a substrate of the maltose-transport system of *Thermococcus litoralis*.

Results shown in Table 3 show that maltose- and glucose-binding activities were highest in extracts from *T. maritima* cells grown with yeast extract added as carbon and energy source. Sugar-binding activity was lowest in extracts of cells grown in the presence of the cognate sugar. Thus, growth of *T. maritima* in the presence of maltose reduced maltose-binding activity to a much greater extent than it reduced glucose-binding activity, while growth in the presence of glucose greatly reduced glucose-binding activity but not maltose-binding activity. Growth of *T. maritima* on either starch or lactose gave higher maltose-binding activity than glucose-binding activity.

At the gross level, these results indicate that the binding proteins are repressed by growth of *T. maritima* in the presence of the cognate sugar. The high binding activities for both sugars in yeast-extract-grown cells might result from the lower concentrations of the sugars in this substrate and their rapid utilization during growth of the organism. Similarly, the observation that binding activities for both maltose and glucose were higher in starch-grown cells than in cells grown on either of the cognate sugars alone might be explained by the rapid utilization with little or no accumulation of maltose or glucose resulting from starch breakdown. Such a regulatory system for binding-protein synthesis, based on repression, would be advantageous for *T. maritima*, a marine organism dependent on carbohydrates that lives in an environment with a low carbohydrate concentration. Enhanced synthesis of the high-affinity binding proteins would allow scavenging of substrate at very low concentrations, while at higher substrate concentrations energy for synthesis of excess binding protein would be conserved.

There have been reports of repression-based control of binding-protein-associated carbohydrate-transport systems in other bacteria. For example, *E. coli* grown at micromolar glucose concentrations in carbon-limited chemostats showed elevated levels of both the methyl galactoside (Mgl) system, an ABC transporter that recognizes glucose with high-affinity and which may in fact be primarily a glucose transporter, and the maltose system. Both systems were strongly repressed when cells of *E. coli* were growing exponentially in millimolar glucose concentrations (Death & Ferenci, 1993, 1994).

Our results do not allow any conclusions regarding the inducibility of the binding proteins, since it has not been possible to grow cells in the absence of carbohydrates. It is possible that endogenous inducer accumulation occurs at very low carbohydrate concentrations as occurs in carbon-limited *E. coli* (Death & Ferenci, 1994).

The annotated *T. maritima* genome sequence shows a large number of ABC carbohydrate transporters (Nelson *et al.*, 1999; Paulsen *et al.*, 2000). The low carbohydrate concentrations in the natural habitat of this bacterium were probably a factor in the selection for these high-affinity systems.

Gel electrophoresis of the maltose-binding protein

Two ORFs, TM1204 and TM1839, were annotated in the *T. maritima* genome sequence as genes encoding putative maltose-binding proteins (*malE1* and *malE2*, respectively) (Nelson *et al.*, 1999). No glucose-binding protein was identified as such in the annotation. Wassenberg *et al.* (2000) reported the cloning and expression of *malE2* in *E. coli* and showed that this gene encodes a maltose-binding protein. We set out to determine whether *malE1* or *malE2* might encode the maltose-binding activity we detected in the cell-free extracts of *T. maritima* by identifying the maltose-binding protein in these extracts.

To identify the protein responsible for maltose binding, we incubated a periplasmic extract of *T. maritima* with \([^{14}C]\)maltose at 55 °C to allow binding. We then resolved the proteins within this extract by PAGE under non-
one maltose-binding protein is present in cells of Thermotoga maritima. With unrelated proteins, it may also be that more than a single maltose-binding protein may simply be mixed together. We were unable to purify this protein further. Although a periplasmic extract provides very little binding protein during subsequent purification steps, consequently, we found that this band apparently consisted of more than one protein, since N-terminal amino acid sequence data indicated a mixture of proteins within the band. An apparent molecular mass of 43 kDa. The size of this band is consistent with the predicted molecular masses of MalE1 and MalE2 (both 43 kDa). However, we found that this band apparently consisted of more than one protein, since N-terminal amino acid sequence data suggested a mixture of proteins within the band. Periplasmic extracts provide very little binding protein and we found the activity of this protein is easily lost during subsequent purification steps; consequently, we were unable to purify this protein further. Although a single maltose-binding protein may simply be mixed with unrelated proteins, it may also be that more than one maltose-binding protein is present in cells of T. maritima. A similar situation was found in Sinorhizobium meliloti, where a genetic approach allowed investigators to determine that at least two trehalose-transporting ABC-transport systems are induced by trehalose (Jensen et al., 2002). A genetic approach would help to differentiate the different binding proteins of T. maritima, but no genetic system allowing directed gene knockouts exists for this organism or any other hyperthermophile.

To identify the transporters used by T. maritima under different growth conditions, expression analyses of all of the binding-protein-encoding genes identified in the genome sequence of this organism during its growth on several different sugars would be very useful. To interpret these data, it will be necessary to assign functions to each of the putative binding proteins identified in the genome sequence through their biochemical characterization. The combination of these data will provide a better understanding of how the evolutionarily important organism T. maritima controls sugar uptake with its large suite of transporters.
