Chlamydial infection has been associated with myocarditis in animals and humans. However, the mechanism resulting in myocarditis following infection is not known. Here, evidence is presented that both Chlamydia trachomatis and Chlamydia pneumoniae can infect and replicate in myocytes isolated from neonate rats. The infected myocytes contained chlamydial inclusions, indicative of chlamydial growth, and infectious particles were recovered from the infected myocytes. It was also found that chlamydial infection at a late stage induced significant damage to the infected myocytes, as evidenced by an increased lactate dehydrogenase release, reactive oxygen species production and a reduced ATP level. However, no nuclear apoptosis was detected in the infected myocytes. Collectively, these observations have demonstrated that Chlamydia spp. are able to both infect and damage myocytes, suggesting a potential role of chlamydial infection in myocarditis.

Keywords: myocarditis, myocytes, chlamydial infection, apoptosis

INTRODUCTION

Chlamydiae are obligate intracellular pathogens that have to replicate inside a cytoplasmic vacuoile of eukaryotic cells. There are three major species of Chlamydia. Chlamydia psittaci is a respiratory pathogen that primarily infects animals, while Chlamydia trachomatis and Chlamydia pneumoniae are human pathogens. C. trachomatis mainly causes ocular and urogenital infections, while C. pneumoniae infects the respiratory tract. More importantly, C. pneumoniae infection has been associated with vascular atherosclerosis (Blessing et al., 2001; Fong et al., 1999; Grayston, 2000; Kalayoglu et al., 2000; Laurila et al., 1997). We have previously demonstrated that respiratory infection with C. pneumoniae but not C. trachomatis can significantly exacerbate atherosclerotic lesions in mouse aorta (Hu et al., 1999; Liu et al., 2000).

Despite the apparent differences in tissue tropism between the chlamydial species, all three major species have been shown to be associated with or to induce myocarditis (Bachmaier et al., 1999; Blessing et al., 2000; Diaz & Collazos, 1997; Fan et al., 1999; Schinkel et al., 1997; Schinkel et al., 2000). Infection with C. psittaci has been demonstrated to not only cause endocarditis in animals but is also infrequently associated with myocarditis in humans working with infected animals (Schinkel et al., 2000). Epidemiological investigations have presented evidence for a role of C. pneumoniae infection in myocarditis and sudden unexpected cardiac death. Not only are C. pneumoniae-specific antibody levels increased in patients with inflammatory heart muscle diseases (Gnarpe et al., 1997), but C. pneumoniae antigens have also been detected in endomyocardial biopsy samples (Wesslen et al., 1992). A C. trachomatis murine strain was demonstrated to cause myocarditis in mice (Bachmaier et al., 1999; Fan et al., 1999). An autoimmune hypothesis was proposed as the potential mechanism of the Chlamydia-induced myocarditis (Bachmaier et al., 1999; Diaz & Collazos, 1997). However, chlamydial organisms were detected in the cardiac tissues of infected subjects, suggesting that the organisms may be able to invade the heart tissues. Thus, it is important to determine whether Chlamydia can actually infect myocytes and cause direct damage to the cardiac tissues. In the present study, we have used rat neonatal myocytes as the model cells to address these questions. We found that C. trachomatis (LGV) and C. pneumoniae (AR39) successfully infected myocytes and produced infectious progeny in myocytes. The chlamydial infection induced lactate dehydrogenase (LDH) release, a clinical indicator of myocarditis, and superoxide production, a known agent that can damage cardiac tissues. The Chlamydia-induced myocyte damage is accompanied with a reduced ATP level. However,
no apparent nuclear apoptosis was detected in the infected myocytes, despite the obvious cellular damage.

**METHODS**

**Preparation of neonate cardiomyocytes.** A myocyte isolation procedure as described previously (Elmadhoun et al., 2001) was followed in this study. Briefly, hearts from 1- to 2-day-old neonatal Sprague–Dawley rats were sterilely harvested and minced into ~1 mm³ pieces on ice, followed by an initial digestion with 0.1% collagenase and 0.15% trypsin (Worthington) in Ca²⁺-, Mg²⁺-free PBS containing 1% glucose at 37 °C for 10 min. After discarding the initial cell-containing supernatant fluid, six additional 10 min digestions were carried out with the same amount of enzymes in DMEM/F-12 medium (abbreviated as DF-12; Life Technologies) with 20% fetal bovine serum (FBS). The cell-containing supernatant fluids from all six digestions were collected and the cells were washed twice with DF-12 by spinning at 300 g for 5 min. Non-myocyte cells were removed by a discontinuous Percoll gradient centrifugation. The cell viability was assessed by trypan blue exclusion and was typically greater than 95%. The isolated cardiomyocytes were cultured in DF-12 with 10% FBS at a density of 0.2–0.5 × 10⁶ cells per well of a 24-well plate in an incubator supplied with 5% CO₂.H₂O. The culture medium was replenished daily. A unique characteristic of the myocytes is that an obvious cellular beating can be seen under an inverted microscope. We found that all visible cell mass uniformly showed beating prior to infection. Four days after culturing, the myocytes were subjected to infection with chlamydial organisms.

**Chlamydial organisms and infection.** The *C. trachomatis* LGV (serovar L2) and *C. pneumoniae* AR39 strains were obtained from Washington Research Foundation, Seattle, USA, and were propagated and purified as described previously (Hu et al., 1999; Zhong et al., 2001). Aliquots of the organisms were frozen at −80 °C before being used for infection. For AR39 infection, the organisms were diluted in DMEM without FBS and inoculated onto cell monolayers in a volume of 200 μl per well at an m.o.i. of 2, or as indicated in individual experiments. After incubation for 2 h at 37 °C, the inoculating solution was removed and 1 ml of DMEM with 10% FBS was added to each well. For L2 infections, the organisms were directly diluted in 10% FBS/DMEM, and 1 ml of the organism-containing solution was added to each well. The organisms were allowed to grow for various periods of time, as indicated in individual experiments. No cycloheximide was added to any of the myocyte infection cultures. After incubation for 2 h at 37 °C, 2% paraformaldehyde/PBS solution for 30 min at room temperature, followed by permeabilization with 0.5% saponin for 30 min at room temperature. After blocking with 1% milk/PBS for 1 h at room temperature, a mouse anti-chlamydial LPS mAb (G. Zhong et al., unpublished data) was used to stain chlamydial antigens. The first antibody staining was visualized with a goat-anti-mouse IgG conjugated with Cy3 (red; Jackson Immunologicals). A DNA dye, Hoechst (blue; Sigma), was used to simultaneously reveal host-cell nuclei. Images were acquired individually for each staining using a SesiCam Imaging System (The Cooke Corporation, NY, USA) connected to a Nikon diaphot inverted microscope and the single colour images were merged in-frame into the dual colour image using the software SIMPLICE. However, for publication purposes, all colour images were flattened into black and white pictures. As a result, only the Cy3 staining (red) of chlamydial inclusions was shown as white on a black background.

**LDH release assay.** LDH activity was measured spectrophotometrically as described by Bergmeyer & Bernt (1974). Aliquots of the culture supernatants from each well were collected and centrifuged for 5 min at 500 g. The supernatant was saved in a sterile microcentrifuge tube and stored at −80 °C. All solutions for this assay were made fresh on the day of the assay. The substrate for the LDH reaction was made by mixing 10% (v/v) NADH and 10% (v/v) pyruvate in Tris/KCl buffer and equilibrated to 25 °C in a water bath prior to use. Quadruplicate 20 μl aliquots of the supernatants (containing LDH) were added to quartz cuvettes containing 800 μl of the substrate solution in a Cary Win UV spectrometer. The change in absorbance at 340 nm is directly proportional to LDH activity in the supernatant samples.

**Detection of ATP levels.** Rat cardiomyocytes with or without chlamydial infection were rinsed twice with cold PBS, and then treated with lysis buffer (0.1 M potassium phosphate, 1% Triton X-100, 1 mM DTT, 2 mM EDTA, pH 7.8) for 15 min at 65 °C. The cell lysates were collected and frozen at −80 °C. The ATP levels in the lysates were determined using a standard firefly luciferase–luciferin bioluminescent assay Kit (Sigma) on a Beckman LS 6500 multi-purpose scintillation counter with single photo monitor. The results were expressed as ATP concentration (nM). Each measurement was carried out in duplicate and two experiments were performed.

**Assessment of oxidative stress.** The intracellular oxidative stress in cardiomyocytes was assessed by monitoring the oxidation of 2,7-dichlorofluorescein diacetate (H2DCF) to highly fluorescent dichlorofluorescein (Swift & Sarvazyan, 2000). Briefly, a 10 mM stock solution of H2DCF (Sigma) was freshly dissolved in ethanol and kept at −20 °C. The stock solution was diluted to 10 μM with PBS (containing both Ca²⁺ and Mg²⁺) prior to the experiment. Rat neonate myocytes were washed twice with warm Ca²⁺-, Mg²⁺-containing PBS and incubated with 10 μM H2DCF (0.5 μl per well of a 24-well plate) at room temperature in the dark. After 20 min incubation, cells were washed twice with PBS to remove the extracellular probe, and image analysis (488 nm excitation wavelength, 515 nm emission wavelength) was conducted immediately using an inverted Nikon microscope with an Axon Integrated Imaging System (Axon Instruments). All images were collected at room temperature. Mean fluorescence intensity of individual cells was calculated by Axon Imaging Workbench Software and the images were
presented in grey scale so that the degree of the intracellular fluorescence brightness is directly proportional to the level of oxidative species in individual cells.

RESULTS

C. trachomatis (L2) and C. pneumoniae (AR39) can infect rat myocytes

Myocyte samples were infected with C. trachomatis L2 or C. pneumoniae AR39, and infection was detected with an immunofluorescence staining assay. As shown in Fig. 1, inclusions filled with chlamydial antigens were detected in the cytosol of myocytes infected with either L2 (at 24 or 48 h post-infection) or AR39 (at 48 h or 72 h post-infection). Since chlamydial infection starts with the entry of a single elementary body (~0.2 μm) into a host cell via endocytosis, a sizeable cytoplasmic inclusion is an indication of chlamydial organism replication inside myocytes. Prior to fixation, we observed that myocytes harbouring chlamydial inclusions were still able to beat, a characteristic of viable cardiomyocytes, although at a lower rate compared to the uninfected cells (data not shown). To determine whether the infected myocytes produce infectious progeny, myocytes infected with either L2 (48 h post-infection) or AR39 (72 h post-infection) were harvested for additional measurements. First, the infected cell pellets were used for making ultrathin sections for electron microscopic observation alone could not allow us to determine whether the infectious particles were still alive. We sonicated the parallel cell pellet samples for measuring the infectivity of the released intracellular particles. The sonicated myocyte lysates were serially diluted in PBS and used to infect HeLa cell monolayers, as described in Methods. The myocyte lysates produced obvious inclusions in HeLa cells (data not shown). We found that the lysates harvested from myocytes infected with 1 × 10⁶ i.f.u. of AR39 organisms generated ~2 × 10⁵ i.f.u. when titrated in HeLa cells, while the lysates of myocytes similarly infected with L2 generated ~1 × 10⁵ i.f.u. Therefore, the burst sizes of AR39 and L2 in myocytes are 20 and 100, respectively. We can, therefore, conclude that C. trachomatis and C. pneumoniae can cause productive infection in rat neonate myocytes.

Chlamydial infection damages myocytes

We next assessed the effects of chlamydial infection on myocyte integrity. Since detection of LDH in blood samples is useful for the diagnosis of myocarditis, we used the LDH release assay to evaluate the potential damage of chlamydial infection on myocytes at various time points post-infection. As shown in Fig. 2, a significant increase in LDH release was found in myocytes 12 h post-infection with C. trachomatis L2 (P<0.05, by comparing to the uninfected control cell samples). As infection continued, more LDH release was detected. These observations suggest that chlamydial infection can cause significant damage to myocyte membrane permeability. To understand how chlamydial infection causes damage to myocytes, we compared the production of oxidative species between infected and

Fig. 1. Infection of myocytes with L2 and AR39. Myocytes were infected and at various time points post-infection, as indicated in each panel, the infected cells were stained with a Chlamydia-specific antibody (bright; visualized with a Cy3-conjugated secondary antibody) and a DNA dye for visualizing host-cell nuclei (not shown due to black and white presentation). Chlamydial inclusions were detected in rat neonate myocytes infected with either C. trachomatis (left panels) or C. pneumoniae (right panels).

Fig. 2. LDH release from Chlamydia-infected myocytes. Myocytes were infected with C. trachomatis L2 at an m.o.i. of 2, and the culture supernatants were harvested at various times post-infection. The results were measured as the absorbance at 340 nm, expressed as the rate of absorbance reduction, and plotted as the percentile of the absorbance reduction rate from the corresponding control groups. Each set of measurements was carried out in quadruplicate and four experiments were performed. Asterisks denote statistically significant differences between the infected and uninfected control samples at the corresponding time points (*, P<0.05; ***, P<0.001; Student’s t-test with two tails).
uninfected cells (Fig. 3). The *C. trachomatis* L2 (Fig. 3a) and the *C. pneumoniae* AR39 (Fig. 3b) infections caused a progressive increase in reactive oxygen species that can oxidize the exogenous marker 2,7-dichlorofluorescein diacetate into dichlorofluorescein as a function of infection time. The fluorescence intensity of the oxidized dichlorofluorescein inside cells correlates well with the levels of intracellular oxidative species. Quantitative analysis by comparing the sizes of oxidized areas on coverslips showed that there was a 1.5- to 3-fold greater increase in oxidative species in the infected cell samples than in the uninfected samples (data not shown). Although it is not known what exactly the measured oxidative species were, it is thought that the major species are hydrogen peroxide and hydroxyl free radical, both of which are known to cause damage to myocyte membrane permeability. Since the ATP level is an indication of cellular viability, we evaluated whether chlamydial infection can affect host-cell ATP production (Fig. 4). We found that the total ATP levels were significantly lower at 30 h post-infection with L2 and at 48 h post-infection with AR39. These observations further confirmed that chlamydial infection caused significant damage to myocytes at the later stage of infection. However, despite the infection-induced damage, there was no apparent nuclear apoptosis in the infected myocytes even at a late stage of infection (Fig. 1; no apparent nuclear condensation was found), which is consistent with our previous observations that *Chlamydia* spp. can actively prevent host cells from undergoing apoptosis (Fan *et al*., 1998).

**DISCUSSION**

Chlamydiae are ubiquitous pathogens that can infect multiple types of hosts at various tissue sites. All three major chlamydial species have been shown to be associated with or to cause inflammation in the heart, suggesting that *Chlamydia* spp. may be able to infect...
heart muscle cells. Although chlamydiae are known to infect both endothelial and smooth muscle cells of the cardiovascular system (Gaydos et al., 1996), it was not known whether Chlamydia spp. could successfully infect myocytes. The present study provided the first experimental evidence showing that chlamydiae are able to productively infect myocytes and cause significant damage to the infected cells.

During epithelial infection of respiratory and urogenital tracts, the Chlamydia-induced diseases are largely due to persistent infection. It is not known whether C. trachomatis or C. pneumoniae can establish persistence in heart muscle cells. Nevertheless, either the direct damage caused by productive infection or the inflammatory response provoked by persistent infection in the heart can be equally fatal to the infected hosts. However, once chlamydiaid organisms are accidentally carried to the heart of the host, chlamydial growth inside the myocytes may cause damage to the heart tissue. This hypothesis is supported by our current finding that chlamydial infection in myocytes induced the production of reactive oxygen species (Fig. 3), agents known to cause cell damage, and triggered release of LDH (Fig. 2), an indicator of cell membrane permeability alteration.
