INTRODUCTION

Reactive oxygen species (ROS) produced as by-products of normal aerobic metabolism are scavenged by a system of both enzymic and non-enzymic antioxidant defences that maintain cellular redox homeostasis (Halliwell & Gutteridge, 1999). When the level of ROS exceeds the antioxidant capacity, redox homeostasis is disrupted, and molecules such as nucleic acids, lipids, proteins and carbohydrates are oxidized. Studies using yeast cells have contributed to the characterization of cellular functions involved in protection against oxidative stress (Jamieson, 1998; Moradas-Ferreira & Costa, 2000; Thorpe \textit{et al.}, 2004), and to the identification of the major protein targets oxidatively inactivated (Cabiscol \textit{et al.}, 2000; Costa \textit{et al.}, 2002; Reverter-Branchat \textit{et al.}, 2004). Protein oxidative modifications include the reversible oxidation of sulphur-containing amino acids, and the irreversible conversion of some amino acids residues to carbonyl derivatives. The oxidation of protein cysteine residues generates sulphenic acid derivatives that are \textit{S}-thiolated with reduced glutathione (Grant \textit{et al.}, 1999; Demasi \textit{et al.}, 2003; Shenton & Grant, 2003), or further oxidized to sulphonic acid moieties. Protein activity is restored by the monothiol glutaredoxin Grx5p (Shenton \textit{et al.}, 2002) or by sulphiredoxin (Biteau \textit{et al.}, 2003), respectively. Protein methionine residues are oxidized to methionine sulphoxide, which can be reduced by methionine sulphoxide reductase (Moskovitz \textit{et al.},...
The accumulation of oxidized proteins has been implicated in the initiation and progression of numerous diseases and ageing (Petropoulos & Friguet, 2005). To prevent the accumulation of irreversibly oxidized proteins, cells have to respond by increasing the rate of proteolysis (Dunlop, 2002). Therefore, protein degradation, in addition to repair, plays a key housekeeping role for eliminating oxidized proteins.

Proteins can be degraded by the proteasome or by vacuolar/lysosomal proteases. The 26S proteasome is assembled by association of the 20S proteasome catalytic core with the 19S regulatory particle. A number of studies have indicated that the 20S proteasome, which degrades proteins in an ATP- and ubiquitin-independent manner, is responsible for the degradation of oxidized proteins. Indeed, ubiquitin-activating and -conjugating enzymes and the 26S proteasome are inhibited during oxidative stress, and cells deficient in ubiquitin-conjugating activity are able to degrade oxidized proteins at near normal rates (Shringarpure et al., 2003). In yeast, exposure to H2O2 increases the activity of the 20S proteasome. Furthermore, cells deficient in the Rpn9p subunit of the 19S regulatory complex exhibit a higher activity of the 20S proteasome, and are able to degrade carboxylated proteins more efficiently than are wild-type cells (Inai & Nishikimi, 2002). The degradation of cytosolic components by lysosomes (autophagy) also plays an essential role in the maintenance of cellular homeostasis (Massey et al., 2004). In mammalian cells, it has recently been shown that a chaperone-mediated autophagy pathway is activated by oxidative stress, and is important for efficient removal of oxidized cytosolic proteins by lysosomes (Kiffin et al., 2004).

The progressive accumulation of malfunctioning cell components during chronological ageing of post-mitotic cells is associated with oxidative damage (Reverter-Branchat et al., 2004; Petropoulos & Friguet, 2005; Vijg & Suh, 2005; Harris et al., 2005) and age-dependent decline of turnover rate and housekeeping (Chen et al., 2004). Consistently, the deletion of UMP1, a gene necessary for 20S proteasome biogenesis, increases constitutive and ageing-induced protein oxidation in yeast (Chen et al., 2004, 2005). The decrease in the activity of both the proteasomal system and the lysosomal proteases, accompanied by an increased accumulation of oxidized proteins, has been observed during senescence of non-dividing fibroblasts (Grune et al., 2005).

In this study, we show that protein fate is a significantly over-represented function induced during recovery of yeast cells after H2O2 stress. In addition to genes encoding subunits of the 20S proteasome, the PEP4 and LAP4 genes, encoding vacuolar proteases, as well as genes associated with protein sorting into the vacuole and vacuolar fusion, were upregulated. Protein turnover increased after oxidative damage by a mechanism partially dependent on Pep4p, which is required for the post-translation precursor maturation of vacuolar proteinases (Woolford et al., 1986). In agreement, the degradation of carboxylated proteins decreased in cells lacking Pep4p. The key role of vacuolar proteolysis in the removal of oxidized cytosolic proteins was further supported by data showing that Pep4p activity increased during chronological ageing, and pep4A mutants showed premature senescence associated with increased accumulation of carboxylated proteins. However, the increased removal of oxidized proteins by PEP4 overexpression was not sufficient to enhance chronological lifespan.

**METHODS**

**Yeast strains and growth conditions.** The following *Saccharomyces cerevisiae* strains were used in this study: W303 (Mata, ade2-1, can1-100, trp1-1, his3-11,15, leu2-3,112) (Wallis et al., 1989), W303 pep4Δ::HIS3 (this work), W303 pDP34 (this work), W303 pDP34-PEP4 (this work) and W303 p416ADH-PEP4-GEF (this work). For PEP4 (=PRA1) disruption, a 3-0 kb deletion fragment containing HIS3 and the flanking regions of PEP4 was used. This fragment was obtained from pKS- pra1AEN::HIS3 (Hirsch et al., 1992), using the following specific primers: reverse (5'-ACACAGGAAACAGCTATGAC-3') and forward (5'-AGGGTTTCCAGTCAGC-3'). Yeast cells were transformed by electroporation. Gene disruption was confirmed by PCR analysis. Yeast cells were grown in YPD [1 % (w/v) yeast extract, 2 % (w/v) bactopeptone, 2 % (w/v) glucose] or in minimal medium [0-67 % (w/v) yeast nitrogen base without amino acids, 2 % (w/v) glucose], supplemented with appropriate amino acids (40 mg tryptophan l-1, 40 mg histidine l-1, 80 mg leucine l-1, 40 mg methionine l-1) and nucleotides (40 mg adenine l-1, 40 mg uracil l-1), to early exponential phase (OD600 0-6) or post-diauxic phase (OD600 7-8 in YPD; OD600 4 in minimal medium), in an orbital shaker, at 26 °C and 120 r.p.m.

**H2O2 recovery and chronological lifespan assay.** In H2O2 recovery experiments, yeast cells were grown in minimal medium to the exponential phase, treated with 1-5 mM H2O2 for 30 min, and centrifuged at 4500 r.p.m. for 5 min. Yeast cells were resuspended in minimal medium lacking H2O2, and allowed to recover for the indicated times. Chronological lifespan was assayed as previously described (Harris et al., 2005). Yeast cells were grown to the post-diauxic phase, centrifuged at 4000 r.p.m. for 5 min, and washed twice with water. Cells were resuspended in water, and incubated at the indicated temperature. Cell viability was determined by standard dilution plate counts on YPD medium containing 1-5 % agar. Colonies were counted after growth at 26 °C for 3 days.

**Glucose assay and enzyme activities.** Glucose in the growth medium was quantified by the glucose/peroxidase method. Samples (2 ml) of cultures were taken and centrifuged at 4500 r.p.m. for 5 min, and supernatants were stored at −20 °C until use. The TGO reagent [0-5 M Tris, pH 7-0, 20 U glucose oxidase ml-1, 0-38 U peroxidase ml-1, 0-05 mg o-dianisidine hydrochloride ml-1, 1 % (v/v) Triton X-100 (2-5 ml) was added to 0-5 ml of sample; the mixture was incubated for 20 min at 37 °C, and the absorbance at 420 nm was measured. Glucose was estimated by reference to a standard curve prepared with known amounts of glucose. For the proteinase A (Pep4p) activity assay, yeast extracts were prepared in 0-1 M Tris, pH 7-5, by vigorous shaking of the cell suspension, in the presence of glass beads, for 5 min. Short pulses of 1 min were used, at 1 min intervals, on ice. Pep4p activity was determined using 0-5 mg total protein, by measuring the release of tyrosine-containing acid-soluble peptides from acid-denatured haemoglobin [expressed as µg Tyr min-1 (mg protein)-1] (Jones, 1990). Glyceraldehyde-3-phosphate dehydrogenase activity (Tdh) was quantified as described by...
Turnover of oxidized proteins in the vacuole

Holland & Westhead (1973), using 25 μg total protein, and expressed as U (mg protein)⁻¹, or as percentage of the control. Protein content of cellular extracts was estimated by the Lowry method, using BSA as a standard.

**Pep4–GFP levels.** Proteins were isolated from S. cerevisiae W303 p416-Pep4–GFP cells, as described for Pep4 activity, and separated by native PAGE (10% gel). After electrophoresis, Pep4–GFP was detected using a molecular imager (Typhoon; Amersham Biosciences Europe). For loading control, proteins were stained with 0-25% (v/v) Coomassie blue R250, 10% (v/v) acetic acid/45% (v/v) methanol, and destained with 10% acetic acid/45% methanol.

**mRNA preparation, synthesis of cDNA, Genefilters hybridization and data analysis.** Total RNA was isolated by the acid-phenol method (Ausubel et al., 1998). Genefilters yeast microarrays (Research Genetics) were hybridized using [³²P]CTP-labelled cDNA, as described previously (Rep et al., 2000). A Molecular Imager FX (Bio-Rad) was used to obtain a digital image of the filters. Images were converted to tagged image file format (TIFF), and the Pathway4 software (Research Genetics) was used for quantification of spot intensities, and for pairwise comparison of gene filter images. Prior to determination of changes in gene expression, all spot intensities were normalized by dividing sampled intensities by the mean sampled intensities of all clones. To determine the fold induction or repression, the relative mRNA level was expressed as the ratio H₂O₂/control (untreated) or recovery/H₂O₂. Genes that changed at least twofold were considered for further analysis. All values are means of the expression profiles of four experiments with similar results, using independent cultures grown or treated under the same conditions. Statistical analysis of the microarray data was performed by using BRB ArrayTools (version 3.3.0 beta1) developed by Richard Simon and Amy Peng Lam (http://linus.nci.nih.gov/BRB-ArrayTools.html). The data were deposited in the microarray data public repository ArrayExpress (http://www.ebi.ac.uk/arrayexpress/) (Parkinson et al., 2005) under the accession number E-MEXP-326. Statistical analysis of over-representation of functional groups was performed by using FUNSPEC (Robinson et al., 2002). All available databases were addressed by using a probability cut-off of 0.01 and the Bonferroni correction for multiple testing.

**Northern blotting.** Total RNA (30 μg) was denatured with glyoxal and DMSO, blotted onto Hybond-N membranes, and probed, as described by Ausubel et al. (1998). The following probes were used: a 1 kb HindIII–EcoRI fragment of the ACTI gene, and a 787 bp fragment of the PEP4 gene amplified by PCR, using PRA1F (5'-GGGAGACTCTTCTTCCACTG-3') and PRA1R (5'-TGCGAGATACAGGAGCCTGA-3') primers. Probes were labelled with [α³²P]dCTP using the Multiprime DNA Labelling System (RPN 1601Z; Amersham Biosciences Europe). Band intensities were evaluated by densitometry.

**Pulse-chase.** Yeast cells (5 ml per sample) were incubated with 3·7 × 10⁵ Bq [³⁵S]methionine ml⁻¹ for 30 min, centrifuged and resuspended in 5 ml minimal medium supplemented with methionine. Yeast extracts were prepared in 50 mM potassium phosphate buffer, pH 7·0, and 0·1 M EDTA, containing a protease inhibitor cocktail (Complete, Mini, EDTA-free Protease Cocktail Inhibitor Tablets; Boehringer Mannheim), by vigorous shaking of the cell suspension, in the presence of glass beads, for 5 min. Short pulses of 1 min were used, at 1 min intervals, on ice. Proteins (500,000 c.p.m.) were separated by SDS-PAGE (12·5% gel). Gels were dried and exposed to an X-ray film. Band intensities were quantified by densitometry.

**Protein carbonylation analysis.** Yeast extracts were prepared in 50 mM potassium phosphate buffer, pH 7·0, and 0·1 M EDTA, containing a protease inhibitor cocktail (Complete, Mini, EDTA-free Protease Cocktail Inhibitor Tablets; Boehringer Mannheim), as described for Pep4 activity. For 1D analysis, proteins (15 μg) were derivatized with 2,4-dinitrophenylhydrazine (DNPH) (Levine et al., 1994), and separated by SDS-PAGE (12·5% polyacrylamide gel). After electrophoresis, proteins were stained with Coomassie blue, or blotted onto Hybond-ECL membranes (Amersham Biosciences Europe). Slot blotting was performed using PVDF membranes (Hybond-PVDF; Amersham Biosciences Europe), as previously described (Costa et al., 2002). The ECL or PVDF membranes were probed with rabbit IgG anti-DNP (Dako) at a 1:5000 dilution as the primary antibody, and goat anti-rabbit IgG–peroxidase (Sigma) at a 1:5000 dilution as the secondary antibody. Immunodetection was performed by chemiluminescence, using a kit from Amersham (RPN 2109). The membranes were exposed to a Hybond-ECL film (Amersham Biosciences Europe) for 15 s to 1 min, and the film was developed. Band intensities were quantified by densitometry.

**RESULTS**

**Protein catabolism is a major function upregulated during recovery after H₂O₂ stress**

Cells exposed to oxidative stress accumulate damaged molecules that have to be repaired or removed before growth is resumed. To understand the molecular mechanisms involved in cellular recovery after oxidative stress, yeast cells were exposed to 1·5 mM H₂O₂ for 30 min, and allowed to recover in fresh minimal medium without H₂O₂. Analysis of cellular viability, measured as percentage c.f.u., showed that 50% of the cells survived and were able to recover after exposure to H₂O₂. Cellular growth was almost completely absent during the first 4–6 h of recovery, subsequently becoming similar to the rate observed in control cells. However, cells remained metabolically active, as glucose consumption still occurred, although at a lower rate (Fig. 1).

To identify cellular functions that might be important for restoring cellular homeostasis, global changes in the transcriptome were analysed in yeast cells allowed to recover for 60 min after H₂O₂ treatment. Exposure to 1·5 mM H₂O₂ triggered a stress response (data not shown) that partially overlapped with that previously described in response to low concentrations (0·2–0·4 mM) of H₂O₂ (Godon et al., 1998; Lee et al., 1999; Gasch et al., 2000). During cellular recovery after H₂O₂ stress (recovery versus H₂O₂) the mRNA level of 99 genes increased, whereas that of another 169 genes (including 88 encoding ribosomal proteins) was diminished (see Supplementary Table S1). Genes up- or down-regulated during recovery that were repressed or induced, respectively, during previous exposure to H₂O₂ were not considered to be specific, because these changes merely restored control mRNA levels. Genes differentially expressed were sorted into functional categories according to the Munich Information Center for Protein Sequences (MIPS). Our data showed that some categories were significantly more represented in cells after recovery, compared to those in H₂O₂-treated cells (Fig. 2): 57% of the genes down-regulated were associated with protein biosynthesis, whereas 32% of the upregulated genes were related to protein fate, and 37% to metabolism. To
identify over-represented biological processes, gene lists were analysed by using the FUNSPEC software (Robinson et al., 2002). Among induced genes, protein catabolism functions had the greatest significance (Table 1). The induction (two- to threefold) of proteolytic activity was correlated with the upregulation of amino acid catabolism, and the down-regulation of amino acid biosynthesis. Genes encoding subunits of the 20S proteasome, as well as some associated with ubiquitin-dependent proteolysis, were found to be upregulated. These results are consistent with published data showing that the 20S proteasome is required for degradation of oxidized proteins (Shringarpure et al., 2003; Inai & Nishikimi, 2002; Chen et al., 2004, 2005).

In addition to proteasome subunits, genes related to vacuolar protein catabolism (PEP4 and LAP4) were induced (two- and 2·5-fold, respectively) during recovery after oxidative damage. The PEP4 gene encodes a vacuolar aspartyl protease that is required for the post-translational precursor maturation of vacuolar proteinases (Woolford et al., 1986). Lap4p is a leucine aminopeptidase that is transported into the vacuole via an autophagosome (Suzuki et al., 2002). Interestingly, genes associated with protein sorting into the vacuole, and with vacuolar fusion (MVP1; 3·3-fold; YHR138C; 2·5-fold; see Supplementary Table S1), were also upregulated.

To confirm the induction of PEP4 gene expression, mRNA-PEP4, Pep4p activity and Pep4p levels were analysed in cells allowed to recover for up to 4 h. The results obtained showed that mRNA-PEP4 and Pep4p protein levels increased during the first 2 h of recovery (Fig. 3a, b). In agreement, Pep4p activity increased twofold (Fig. 3b). After 4 h of recovery, mRNA-PEP4 returned to control levels; however, Pep4p levels and enzyme activity remained high. This transient upregulation of PEP4 gene expression, leading to a more sustained increase in protein and enzyme activity, suggests that Pep4p is stable and has a long half-life.

The vacuolar protease Pep4p contributes to protein catabolism after oxidative damage

The upregulation of genes associated with protein catabolism suggests that cells respond to protein oxidative damage by increasing protein turnover. To test this hypothesis,

![Fig. 1. Cellular growth and glucose consumption during recovery of S. cerevisiae cells from H2O2 stress. S. cerevisiae W303 cells were grown in minimal medium to the exponential phase (OD600 ~0·6). Control (●) and cells treated with 1·5 mM H2O2 for 30 min (▲) were centrifuged and resuspended in minimal medium without H2O2. Cell density (a) and percentage (w/v) glucose remaining in the growth medium (b) were determined during cellular recovery up to 24 h. Values are means ± SD of three independent experiments.](image1)

![Fig. 2. Functional grouping of genes differentially expressed during recovery from H2O2 stress. S. cerevisiae W303 cells were exposed to 1·5 mM H2O2 for 30 min, and allowed to recover in H2O2-free medium for 60 min. Whole-transcriptome changes (recovery versus H2O2) were analysed using Genefilters (Research Genetics). Genes down-regulated (total 169) or upregulated (total 99) were sorted into functional categories according to the MIPS database. See Supplementary Table S1 for all data. Met, metabolism; Prot, protein biosynthesis; PF, protein fate; CT, cellular transport, transport facilitation and transport routes; CRD, cell rescue, defence and virulence; CTD, cell type differentiation; O/U, other/uncharacterized.](image2)
Table 1. Functional categories over-represented in microarray data on cell recovery after H$_2$O$_2$ stress, according to the Gene Ontology (GO) database (see Supplementary Table S1 for all data)

Gene lists were analysed by FUNSPEC (Robinson et al., 2002). P values represent the probability that the intersection of a given list of genes with any given functional category occurs by chance. ‘e’ is the base of natural logarithms.

S. cerevisiae W303 cells were pulse-chased with [35S]methionine and the fate of [35S]-labelled proteins was assessed during recovery from H$_2$O$_2$ stress. The results showed that protein turnover increased after H$_2$O$_2$-induced damage (Fig. 4a). In control cells (untreated), protein degradation was not observed up to 4 h of recovery (data not shown).

The requirement of de novo protein synthesis to restore damaged protein function is consistent with the metabolic activity of the cells. As Tdh is a major target inactivated during exposure to H$_2$O$_2$, by both S-glutathionylation and carbonylation, this protein was used as a biomarker to assess the contribution of de novo protein synthesis to the recovery of enzyme activity. Protein carbonylation, in contrast to S-glutathionylation, is irreversible. Thus, Tdh dethiolation contributes to, but may be insufficient to fully restore, Tdh activity when cells return to non-stress conditions. To test this hypothesis, Tdh activity was initially measured in protein extracts prepared from controls and cells exposed to H$_2$O$_2$. The effect of Tdh dethiolation on enzyme activity was investigated by treating extracts from cells exposed to H$_2$O$_2$ with the reducing agent DTT (25 mM). In H$_2$O$_2$-treated cells, Tdh activity decreased to 41·1±0·7% of that in untreated cells. In vitro Tdh dethiolation led to a partial increase in Tdh activity up to 56·6±6·0% of that in untreated cells ($P<0·01$). The importance of de novo protein synthesis was studied in vivo by assessing the effect of cycloheximide in the recovery of Tdh activity. In the absence of this protein synthesis inhibitor, Tdh activity increased to 80% of control levels after 6 h of recovery (Fig. 5). In cycloheximide-treated cells, Tdh activity increased to <60% of control levels (Fig. 5). Interestingly, Tdh activity after cell recovery was similar to that achieved by in vitro dethiolation. These results indicate that de novo protein synthesis contributes to restoration of the active enzyme.

Proteolysis can be carried out by proteasomes or by vacuolar proteases. The role of the 20S proteasome in degradation of oxidized proteins has been reported elsewhere (Inai & Nishikimi, 2002). As PEP4 and LAP4 genes were induced, and Pep4p activity increased during recovery from H$_2$O$_2$ stress, we raised the hypothesis that vacuolar proteolysis contributes to protein turnover after oxidative damage. To test this hypothesis, the PEP4 gene was disrupted by homologous recombination, and the rate of protein degradation in pep4Δ mutants was compared with that of parental cells. Notably, loss of Pep4p significantly decreased protein degradation during cellular recovery (Fig. 4a). The correlation between protein turnover and removal of oxidized proteins was further analysed by measuring protein carbonyl content. Consistent with earlier studies (Inai &
Nishikimi 2002), protein carbonylation increased during exposure of parental cells to 1–5 mM H$_2$O$_2$ for 30 min, and allowed to recover in H$_2$O$_2$-free minimal medium for up to 4 h. (a) Northern blot analysis. The mRNA-PEP4 hybridization signal was quantified by densitometry, and corrected for ACT1 (RNA loading control). Values are fold-changes relative to those in untreated cells. Results of a representative experiment are shown (out of three independent experiments). (b) Pep4 activity and protein levels. Pep4 activity was determined as described in Methods, and expressed as the ratio recovery/control (untreated cells). Pep4 activity in control cells was 1.1 ± 0.2 mg Tyr min$^{-1}$ (mg protein)$^{-1}$. For the analysis of Pep4 levels, proteins were isolated from yeast cells expressing Pep4–GFP and separated by native PAGE. Fluorescence was detected using a molecular imager. The gel was stained with Coomassie blue (loading control; only a region of the gel is shown). Results of a representative experiment are shown (out of three independent experiments). Values are means ± SD of three independent experiments. *P<0.05, **P<0.01 [recovery versus H$_2$O$_2$ ($t_0$)].

Fig. 3. Analysis of Pep4 levels (mRNA, activity and protein) during recovery from H$_2$O$_2$ stress. S. cerevisiae W303 cells were treated with 1–5 mM H$_2$O$_2$ for 30 min, and allowed to recover in H$_2$O$_2$-free minimal medium for up to 4 h. (a) Northern blot analysis. The mRNA-PEP4 hybridization signal was quantified by densitometry, and corrected for ACT1 (RNA loading control). Values are fold-changes relative to those in untreated cells. Results of a representative experiment are shown (out of three independent experiments). (b) Pep4 activity and protein levels. Pep4 activity was determined as described in Methods, and expressed as the ratio recovery/control (untreated cells). Pep4 activity in control cells was 1.1 ± 0.2 mg Tyr min$^{-1}$ (mg protein)$^{-1}$. For the analysis of Pep4 levels, proteins were isolated from yeast cells expressing Pep4–GFP and separated by native PAGE. Fluorescence was detected using a molecular imager. Values are means ± SD of three independent experiments. *P<0.05, **P<0.01 [recovery versus H$_2$O$_2$ ($t_0$)].

Pep4 led to an increase in the basal levels of protein carbonyl groups. The analysis of carbonyl content by slot blot analysis confirmed this increase (146 ± 14 %, pep4Δ versus W303, P<0.001; data not shown). Furthermore, although H$_2$O$_2$-induced protein carbonylation in the pep4Δ mutants was of the same order of magnitude as that of the parental strain, the decrease in carbonyl content during cellular recovery occurred at a much lower rate (Fig. 4b).
The accumulation of oxidized molecules is a characteristic feature of cells undergoing oxidative stress. Cells recovering from acute oxidative stress have to repair or degrade the damaged molecules. To identify genes that are important for restoring cellular homeostasis, whole-transcriptome changes were analysed during recovery of yeast cells after H2O2 stress. Most of the genes specifically repressed were related to amino acid and protein biosynthesis. It is likely that these changes help to preserve mass and energy for use in housekeeping activities that are critical to restore internal homeostasis. Indeed, cellular growth was impaired, and among the genes induced during recovery, protein catabolism was the most significantly over-represented function. In agreement, the rate of proteolysis increased during recovery after oxidative damage, and concomitantly, protein carbonyl content decreased. Tdh is a major target that is carbonylated in cells treated with H2O2 (Cabiscol et al., 2000; Costa et al., 2002). Supporting the hypothesis that protein turnover is important for cellular recovery after
oxidative damage, we showed that de novo protein synthesis contributes to restoring Tdh activity.

Several studies have indicated that the 20S proteasome plays a key role in the removal of irreversibly oxidized proteins (Shringarpure et al., 2003; Inai & Nishikimi, 2002). In agreement, the expression of several genes encoding 20S proteasome subunits (PRE3, PRE6, PRE7, PRE9 and UMP1) increased during recovery. Although we also observed the induction of genes encoding ubiquitin-activation (UBA1)

Fig. 6. Role of Pep4p in chronological lifespan. Yeast cells were grown in YPD medium to post-diauxic phase, and growth-arrested in water at 37 °C. (a) Chronological lifespan was analysed in S. cerevisiae W303 (▲) and pep4Δ (■) cells by measuring cell viability on the days indicated. (b) Carbonyl content in W303 (open bars) and pep4Δ (closed bars) cells. Proteins were isolated from control and aged yeast cells, derivatized with DNPH, and slot-blotted onto Hybond-PVDF membranes. Immunodetection was performed using an anti-DNP antibody, as described in Methods. Band intensities were quantified by densitometry. (c) Pep4p activity was determined in S. cerevisiae W303 cells, as described in Methods, and expressed as the ratio aged/control. Pep4p activity in control cells was 3.4 ± 0.1 mg Tyr min⁻¹ (mg protein)⁻¹. Values are means ± SD of three independent experiments; *P < 0.01 (pep4Δ versus W303 cells), **P < 0.01 (aged versus control).

Fig. 7. Effect of Pep4p overexpression on chronological lifespan. S. cerevisiae W303 pDP34 (▲) and pDP34-PEP4 (■) cells were grown in minimal medium to post-diauxic phase, and growth-arrested in water at 30 °C. Chronological lifespan (a) and carbonyl content (b) were measured as described in the legend to Fig. 6. Values are means ± SD of three independent experiments; *P < 0.05, **P < 0.01 (W303 pDP34 versus pDP34-PEP4 cells).
and -conjugation (UBC1, RAD6) enzymes, a ubiquitin-specific protease (UBP6) and one 26S proteasome subunit (UBC13), the degradation of carbonylated proteins does not require ubiquitination. Indeed, cells deficient in Doa4p, which contain reduced levels of free ubiquitin (Swaminathan et al., 1999), degrade carbonylated proteins as efficiently as do parental cells (data not shown), and protein multi-ubiquitination is not observed in H$_2$O$_2$-treated cells (Inai & Nishikimi, 2002).

Our data show that genes associated with vacuolar proteolysis are also upregulated during recovery after oxidative damage. These include PEP4, which encodes a vacuolar aspartyl protease required for the post-translational precursor maturation of vacuolar proteinases (Woolford et al., 1986), and LAP4, which encodes a vacuolar aminopeptidase, as well as genes related to protein sorting into the vacuole, and to vacuolar fusion. Consistent with a role for vacuolar proteolysis in cellular recovery from oxidative damage, Pep4p levels and enzyme activity increased during recovery, and this induction was correlated with a higher rate of proteolysis, and a decrease in protein carbonyl content. In addition, the protein degradation rate and the capacity to remove oxidized proteins decreased in pep4Δ mutants. Importantly, the oxidized protein level was constitutively higher in pep4Δ mutants, indicating that vacuolar proteolysis has a major role in the turnover of proteins oxidized by endogenously generated or exogenously added ROS. These results are in agreement with data suggesting that protein sorting, vacuole function and vacuolar acidification are core functions required for broad resistance to oxidative stress in yeast (Thorpe et al., 2004). In yeast, a mechanism of transport into the vacuole independent of the secretory pathway has been described for a few cytosolic proteins, namely the gluconeogenic enzyme fructose-1,6-bisphosphatase (Brown et al., 2000) and the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (Horst et al., 1999). Members of the Hsp70 family play a role in the import of these cytosolic proteins into the vacuole. In mammalian cells, it has recently been shown that a chaperone-mediated autophagy pathway is activated by oxidative stress, and contributes to degradation of oxidized cytoplasmic proteins inside the lysosomes (Kiffin et al., 2004). The present study identified several genes associated with protein folding and stabilization that are upregulated during recovery after H$_2$O$_2$ stress, and therefore, might be important for the selective import of oxidized proteins into the vacuole. However, it has recently been shown that cells treated with H$_2$O$_2$ release Pep4p into the cytoplasm (Mason et al., 2005). It is therefore conceivable that oxidized proteins may be degraded by Pep4p in the cytoplasm.

Studies in yeast and other model organisms have shown that the increased scavenging of ROS by overexpression of antioxidant defences delays ageing (Sun et al., 2002; Harris et al., 2003, 2005), and defective removal of damaged proteins by the 20S proteasome promotes senescence (Chen et al., 2004, 2005). The key role of Pep4p in the turnover of damaged proteins after oxidative stress led us to investigate if this homeostatic function is important for chronological lifespan. It has been shown that Pep4p is important for survival of stationary cells, as it recycles nitrogen in starved cells (Teichert et al., 1989; Levine & Klionsky, 2004). The present study showed that the premature senescence of pep4Δ mutants was associated with increased accumulation of carbonylated proteins. It should be noted that protein carbonyl content in the parent strain at day 15, when cells began to lose viability, was 1.8-fold higher than the amount in aged pep4Δ mutants (day 2) (Fig. 6b). The dramatic shortening of the chronological lifespan in cells lacking Pep4p was probably due to the sum of two detrimental effects: nitrogen starvation and accumulation of damaged proteins.

In parental cells, Pep4p activity increased during cell ageing, indicating that lifespan was not limited by the loss of Pep4p function. Thus, protein oxidation rate may exceed the capacity of aged cells to degrade oxidized proteins in the vacuole. A progressive decline in the capacity to deliver cargo into the vacuole would also explain these results. Interestingly, orthologues of yeast autophagy genes are essential for lifespan extension by calorie restriction, and for the increased longevity of Caenorhabditis elegans mutants with defective Daf-2 protein, an insulin receptor analogue (Melendez et al., 2003).

The steady accumulation of carbonylated proteins over time was prevented in cells overexpressing PEP4, supporting the role of Pep4p in the turnover of oxidized proteins. Despite this, the increased Pep4p activity did not extend yeast chronological lifespan. These results indicate that removal of oxidized proteins is not the (only) limiting factor in lifespan. This may be explained by the fact that increased levels of Pep4p do not prevent the increase of other hallmarks of cell ageing, such as lipid peroxidation and oxidative DNA damage (Halliwell & Gutteridge, 1999). In contrast, overexpression of free-radical-scavenging enzymes (primary defences) decreases intracellular oxidation, preventing oxidative damage to cellular molecules, and therefore extending lifespan (Sun et al., 2002; Harris et al., 2003, 2005). Nevertheless, this does not exclude the hypothesis that the accumulation of oxidized proteins promotes cell death associated with ageing.

In summary, the overall results indicate that vacuolar proteolysis contributes to the efficient removal of proteins oxidized during exposure to H$_2$O$_2$, or by ROS generated as by-products of normal aerobic metabolism. This work also provides new evidence that failure to complete housekeeping due to defective vacuolar proteolysis contributes to the progressive accumulation of molecular damage associated with chronological ageing. However, removal of oxidized proteins is not the only limiting factor, as PEP4 overexpression prevents the accumulation of carbonylated proteins, but is not sufficient to extend lifespan.
ACKNOWLEDGEMENTS

M. M. thanks Fundação para a Ciência e a Tecnologia (FCT) for a PRAXIS BD grant, and the project was financially supported by FCT/Project PRAXIS/P/BIA/102641/1998. The authors thank Professor Dieter H. Wolf (University of Stuttgart) for generously providing pKS-prATEN::HIS3, pDP34 and pDP34-PEP4, and Professor D. S. Goldfarb (University of Rochester) for p416ADH-PEP4-GFP.
