Flagellar glycosylation – a new component of the motility repertoire?

Susan M. Logan

Institute for Biological Sciences, National Research Council, Ottawa, Ontario K1A OR6, Canada

The biosynthesis, assembly and regulation of the flagellar apparatus has been the subject of extensive studies over many decades, with considerable attention devoted to the peritrichous flagella of *Escherichia coli* and *Salmonella enterica*. The characterization of flagellar systems from many other bacterial species has revealed subtle yet distinct differences in composition, regulation and mode of assembly of this important subcellular structure. Glycosylation of the major structural protein, the flagellin, has been shown most recently to be an important component of numerous flagellar systems in both Archaea and Bacteria, playing either an integral role in assembly or for a number of bacterial pathogens a role in virulence. This review focuses on the structural diversity in flagellar glycosylation systems and demonstrates that as a consequence of the unique assembly processes, the type of glycosidic linkage found on archaeal and bacterial flagellins is distinctive.

Introduction

The bacterial flagellum, a key component of bacterial motility, is recognized as playing a vital role in the exquisite ability of many bacteria to adapt to the great diversity of biological niches in which they are found. This diversity includes aquatic and soil environments as well as the unique microenvironments which bacterial pathogens colonize within their respective protozoal, plant or animal host(s). While the model organisms for understanding the process of flagellar biosynthesis, assembly and regulation have been *Salmonella enterica* serovar Typhimurium strain LT2 and *Escherichia coli* K-12 (Aldridge & Hughes, 2002; Macnab, 2003), both of which produce peritrichous flagella composed of a single flagelin structural protein (simple flagella), recent post-genomic analysis has indicated that this existing paradigm reflects in general terms a degree of structural and regulatory conservation across the bacterial phyla (Pallen et al., 2005). However, the definitive contribution of the flagellar organelle to numerous unique bacterial lifestyles remains to be established. It is possible that the well-established paradigm defined by the motility systems of these two organisms may not be adequately encompassing for flagellar/motility systems from many distantly related bacterial species or indeed for alternative structures (lateral, polar or periplasmic flagella) of more closely related organisms. A recent body of work has described the process of flagellar glycosylation in a diverse number of bacterial species and in some cases has demonstrated a role for this process in both flagellar assembly and biological function. While it may be premature to consider glycosylation as a component of the flagellar repertoire, the intent of this review is to provide a current update on the extent of flagellar glycosylation in both Bacteria and Archaea, and to demonstrate that for a number of motile organisms it does appear to play a significant role both in flagellar assembly and in interactions of organisms with their surroundings.

Flagellar structures

A variety of flagellar structures other than the peritrichous, simple flagella commonly found on enteric bacteria have been described and are the subject of a number of recent detailed reviews to which the reader is referred (Bardy et al., 2003; Charon & Goldstein, 2002; McCarter, 2001, 2004). It is noteworthy that a significant number of the flagellin structural protein monomers which are part of these alternative flagellar structures have recently been shown to be glycosylated at multiple sites (Table 1). As thousands of copies of these proteins are present within an assembled filament the biological role of these novel glycan components should not be overlooked. A brief summary of each of these alternative structures is presented.

A diverse range of bacterial species when grown in liquid medium will produce flagella which are described as polar. Both simple, polar flagella (e.g. *Legionella pneumophila*, *Pseudomonas aeruginosa*) and complex (more than one flagellin protein monomer) polar flagella (e.g. *Caulobacter crescentus*) have been described and these are found as either a single filament (monotrichous) or in a bundle (multitrichous) at either one or both (bipolar) ends of the cell. In addition, some organisms produce flagella which are covered with an external layer, the sheath (e.g. *Vibrio parahaemolyticus*). This structure has been described as an extension of the outer membrane, although in some cases it has been shown to be unique in composition (Doig & Trust, 1994; Fuerst, 1980; Geis et al., 1993; Hranitzky et al., 1980;

Electron microscopy studies of a number of organisms with polar flagella have identified, in addition, a unique basal body structure which appears to be a convex disk situated below the outer membrane (Engelhardt et al., 1993; Ferris et al., 1984; Thomashow & Rittenberg, 1985b). It remains to be established if this is an integral component of all polar structures and what role it contributes to the functioning of the polar flagellum.

As with the peritrichous flagella of enteric bacteria, lateral flagella (laf) are visible as a number of filaments extending at random points on the cell but not from either of the cell poles. Laf are in most cases composed of more than one flagellin structural protein and are induced when cells are grown on solid surfaces, where they have been shown to facilitate swarming. In most cases, organisms which produce these distinct peritrichous flagella are also capable of producing polar flagella when grown in broth.

In distinct contrast to these surface-expressed motility systems, the motility of spirochaetes is mediated by unique periplasmic flagella (Charon & Goldstein, 2002). These flagellar organelles are attached subterminally to each end of the cell cylinder and the flagella function by rotating within the periplasmic space. A number of features distinguish these periplasmic flagella from the flagella of enteric bacteria, most notably the lack of L and P rings in the basal body as well as the composition of the flagellar filament. The filament is of the complex type, composed of a family of FlaB core proteins, and may be enveloped by a structure described as a sheath which is composed of only a single FlaA structural protein. FlaB core proteins share N- and C-terminal homology with other bacterial flagellins while the FlaA protein bears no sequence similarity. FlaA is likely secreted to the periplasmic space by the Sec secretory pathway while FlaB secretion occurs through the basal body of the flagellar type III secretory apparatus (Brahamsha & Greenberg, 1988; Li et al., 2000).

Finally, while flagellar-based motility is also a common feature of the Archaea, the structure produced in this kingdom is unique and more closely resembles type IV bacterial pili in its structure and mode of assembly (Bardy et al., 2004). The flagellar filament is generally complex in nature and composed of multiple flagellin structural proteins. Unlike bacterial flagellins, archaeal flagellin is expressed as a preflagellin protein with a leader peptide sequence which is cleaved by a signal peptidase to produce mature flagellin. This mature protein is secreted from the cell and incorporated at the base of the filament, a process which is in distinct contrast to the bacterial system, where flagellin is incorporated at the distal end of the growing filament.

### Glycoprotein structural analysis

As a consequence of methodological advances in glycoprotein characterization (Dell & Morris, 2001), considerable progress has been made in the structural characterization of flagellar glycans, most notably those from polar flagella of...
numerous Gram-negative bacteria. Mass spectrometry plays an integral part in the analysis of any novel glycoprotein, yet in the case of prokaryotic glycoproteins the presence of novel monosaccharides often in limited quantities presents unique challenges for structural analysis. However, with the increased sensitivity of mass spectrometers and recent advances in NMR technology, it is now possible to obtain detailed structural characterization from nanomolar amounts of purified glycan (Voisin et al., 2005). Initial analysis of a putative flagellar glycoprotein is the determination of the intact mass by either MALDI-TOF MS or ESI-MS. This provides preliminary information on the degree of glycosylation when prior sequence information is available. Recently, a ‘top-down’ approach has been used to provide more information on the novel O-linked glycans found on bacterial flagellins (Schirm et al., 2005). In brief, the labile nature of the glycosidic bond favours cleavage of O-linked glycans from glycoproteins when they are subjected to low-collision activation. Structural information is obtained on individual carbohydrate residues using a second-generation product ion scan of oxonium ions formed from this collisional activation of the intact protein ions. As an initial screening tool to establish the glycosylation status of novel proteins this approach requires minimal sample preparation and takes a relatively short time. More sophisticated ‘top-down’ approaches are possible using high-end mass spectrometry instruments, such as Fourier-transform ion cyclotron resonance mass spectrometry (FT-MS).

However, to precisely assign the type and location of the post-translational modifications a ‘bottom-up’ approach is most commonly utilized (Wysocki et al., 2005). This involves proteolytic cleavage of the original glycoprotein and separation of the corresponding products by liquid chromatography coupled to mass spectrometry (LC-MS) or capillary electrophoresis-nanoelectrospray mass spectrometry (CE-MS). The majority of the peptides will be readily identified based on mass alone at this stage; however, those that are not will then be examined by tandem mass spectroscopy (MS-MS). Glycopeptides display unique fragmentation patterns due to the labile nature of glycosidic bonds, and MS-MS spectra are typically dominated by fragment ions specific to the respective glycan. Accurate mass measurements of glycan oxonium ions provide plausible empirical formulae. To determine the glycan linkage site, either β-elimination experiments (for O-linked glycans) (Rademaker & Thomas-Oates, 1996), where base-catalysed hydrolysis results in the incorporation of a newly formed amino group of distinct mass at the linkage site, or MS² on individual glycopeptides (for N-linked glycans) can be performed. NMR has proven to be the most powerful technique for the definitive structural assignment of the novel prokaryotic glycans identified to date.

**Flagellar glycosylation**

**Archaea.** The glycosylation of archaeal flagellin is extensive throughout the kingdom although in the majority of examples only presumptive evidence based on glycoprotein-specific staining of the purified flagellin proteins is currently available. The exceptions are the flagellins of *Halobacter salinarum* and *Methanococcus voltae*. The first structural characterization of a flagellar glycan was provided by Wieland et al. (1985) for the flagellin of *H. salinarum*. The flagellin proteins were shown to be glycosylated in identical fashion to that of the cell surface S-layer proteins, with sulphated glucuronic acids through N-glycosidic linkage. More recently, a complete structural characterization of flagellin proteins from *M. voltae* has revealed the presence of a novel trisaccharide of mass 779 Da attached at each N-linked sequon (Asn-X-Set/Thr) of the four flagellar structural proteins (Voisin et al., 2005). The structure of this novel glycan was determined by NMR and shown to be a trisaccharide composed of β-ManpNAcA6Thr-(1-4)-β-GlcNAc3NAcA-(1-3)-β-GlcNAc linked to Asn. As was the case for *H. salinarum*, the same trisaccharide was shown to be decorating the S-layer protein of *M. voltae*, implicating a common N-linked glycosylation pathway for these two major surface protein structures in the Archaea. The genetic basis for these processes remains ill defined at present.

**Gram-negative bacteria**

In addition to the numerous examples of motile organisms in aquatic environments, the gastrointestinal tract of humans and animals is host to both bacterial pathogens and natural flora, many of which require motility for effective colonization. Within this unique biological niche, a number of examples of flagellin glycosylation have recently become apparent. The genetics of flagellar glycosylation systems was recently included in a review of protein glycosylation in Gram-negative bacteria (Power & Jennings, 2003).

**Campylobacter spp.** Probably the best-characterized polar flagellar glycosylation system is that of *Campylobacter jejuni*, a human gastrointestinal pathogen which produces bipolar flagella composed of two structural proteins FlAA and FlAB and which has recently been the subject of numerous reviews (Szymanski et al., 2003; Szymanski & Wren, 2005). Motility of Campylobacter is essential for colonization of the viscous intestinal mucus in the human host (Black et al., 1988) and the flagellin protein is the immunodominant antigen on the cell surface. While the post-translational modification of Campylobacter flagellin had been described by Logan et al. (1989), and Ait et al. (1992) demonstrated variability in the mass of FlAA protein in different Campylobacter host backgrounds suggestive of variability in modifications amongst strains, it only became apparent that the protein was modified through glycosylation after the demonstration of sensitivity of the flagellin protein to periodic acid and a capacity to bind a sialic-acid-specific lectin (Doig et al., 1996). The definitive structural characterization of the FlAA protein was provided by Thibault et al. (2001). Campylobacter flagellins are the most heavily glycosylated flagellins characterized to date, with up to 19 sites in each FlAA monomer decorated in O-linkage at
serine or threonine residues with the novel ‘sialic acid like’ monosaccharide 5,7-diacetamido-3,5,7,9-tetrae oxy-L-glycero-L-manno-nonulosonic acid (pseudaminic acid, Pse) and its acetamido derivative (PseAm) along with minor quantities of a number of related derivatives made by individual strains (Logan et al., 2002; Schirm et al., 2005; Thibault et al., 2001). The FlaB protein is glycosylated in a similar fashion (unpublished observation). The sites of modification are localized to the central region of the primary sequence which, based on the crystal structure of flagellin from S. enterica, is predicted to be surface exposed in the assembled filament (Samatey et al., 2000).

Extensive genetic characterization (Goon et al., 2003; Guerry et al., 1996; Linton et al., 2000; Logan et al., 2002; Thibault et al., 2001) and the determination of the genome sequence of C. jejuni 11168 (Parkhill et al., 2000) has revealed a genetic locus of approximately 50 genes, including the flaA and flaB structural genes, which is responsible for this glycosylation. Campylobacter isolates display significant genetic diversity within this locus, which has been shown to be responsible for the antigenically distinct PseAm glycan variants produced by individual strains (Logan et al., 2002). Most recently, comparative phylogenomics revealed a cluster of six genes within this locus to be a specific marker for a ‘livestock’ clade (Champion et al., 2005), although the role of these genes in production of a unique glycoform relevant to adhesion in the livestock gut has yet to be demonstrated. The annotation of the locus suggested that approximately 50% of the genes were likely to be involved in carbohydrate biosynthetic pathways and that some of them had homology to sialic acid biosynthesis genes (neuA, neuB, neuC). Several studies, including structural investigations of flagellin from isogenic mutants (Creuzenet, 2004; Goon et al., 2003; Logan et al., 2002; Obhi & Creuzenet, 2005; Thibault et al., 2001) and a novel metabolomic analysis (Soo et al., 2004), have provided proof that a number of these biosynthetic genes are indeed involved in the biosynthetic pathway of either Pse or PseAm.

It is significant that while the function of the key enzymes PseB, PseC and NeuB in the biosynthetic pathway of Pse have recently been elucidated in detail (Chou et al., 2005; Schoenhofen et al., 2006) the identification and characterization of the glycosyltransferase(s) responsible for the addition of these novel monosaccharides to the flagellin protein remains elusive. No obvious candidate gene is apparent in the flagellar glycosylation locus although the homologue of fliD (Cj1312) from the Caulobacter crescentus flagellar glycosylation locus (see below) may be a potential candidate.

A unique feature of the glycosylation locus is the presence of multiple copies of hypothetical genes encoding proteins belonging to the motility accessory family (Maf) of flagellin-associated proteins, which have homologues in only a limited number of bacterial species, including Helicobacter, Wolinella and Clostridium spp. There are seven members of these genes in the C. jejuni 11168 locus, yet, while several Maf members have been shown to be involved in motility (Karlyshev et al., 2002), the specific role of these proteins in the glycosylation process is currently unknown. A second paralogous gene family, the 617 family, includes four members in the glycosylation locus of C. jejuni 11168 (Cj1305, Cj1306, Cj1310 and Cj1342). As with the Maf family of proteins, slipped-strand mispairing appears to lead to phase-variable gene expression. To date no homologues of the 617 family have been found in other bacterial species.

In contrast to the assembly process of peritrichous flagella of the enteric bacteria, the glycosylation of Campylobacter flagellin is essential for flagellar assembly and consequent motility. Mutants in Pse biosynthetic genes in several strains of Campylobacter are non-motile and accumulate intracellularly flagellin of reduced molecular mass (Goon et al., 2003). Analysis of the flagellin by mass spectroscopy confirmed the lack of any glycosylation, providing specific proof of a functional role for the glycosylation process in flagellar assembly. Significantly, one of the key Pse biosynthetic genes, pseB, is under the control of a σ28 promoter (Goon et al., 2003) which is well recognized as the late-stage regulator within the flagellar regulon, and a number of other flagellar glycosylation genes have been shown by bioinformatics analysis to lie downstream of σ28-dependent promoter sequences (Carrillo et al., 2004). This coregulation of flagellar glycosylation genes by the two key transcriptional regulators for the flagellar regulon emphasizes the integral role played by this process in the assembly of a functional filament.

*Helicobacter* spp. In contrast to Campylobacter, the complex flagella of *Helicobacter* spp. are assembled at one or both poles of the cell as either a single flagellum or a bundle of filaments, which in some cases are enveloped in an external sheath (Fox, 2002). In *Helicobacter pylori*, the human gastric pathogen, the flagellar filament is unique in appearance due to the presence of a terminal bulb at the distal end of each filament. Members of the genus have been isolated from the stomachs, intestines and caeca of humans and numerous animal species. Motility is essential for colonization of these diverse mucosal surfaces (Eaton et al., 1996; Andrusit et al., 1997). The first evidence that the flagellin of this genus was glycosylated was provided by Josenhans et al. (1999) in studies on *Helicobacter felis*. Subsequent studies (Josenhans et al., 2002) demonstrated glycosylation of flagellin from *H. pylori* and in addition identified two genes HP0326a and HP0326b, homologues of the Campylobacter flagellar glycosylation genes Cj1311 (neuA) and Cj1312 (fliD), which appeared to be involved in the glycosylation process. The detailed structural characterization of *H. pylori* flagellin revealed that both the FlaA and FlaB structural proteins were glycosylated in *H. pylori* (Schirm et al., 2003, 2005) in a similar manner to *C. jejuni*, with Pse found at seven sites on the FlaA protein and ten sites on the FlaB protein. A significant difference in the modification profile is the lack of heterogeneity in the composition of glycans found on *H. pylori* flagellin. It is possible that the presence of...
the flagellar sheath in this organism may indeed reduce the need for Helicobacter cells to invest significant resources in the production of a number of diverse, novel glycosylated structures. Correspondingly, in contrast to Campylobacter, bioinformatics studies have indicated a far simpler glycosylation gene content, and the functional characterization of a number of these genes has defined their roles in the Pse biosynthetic pathway. The biosynthetic genes HP0840, HP0178, HP0326A and HP0326B and HP0366 have received considerable attention (Creuzenet et al., 2000; Merkx-Jacques et al., 2004; Schirm et al., 2003; Schoenhofen et al., 2006) and their role in the biosynthesis of Pse is now clearly established. The genome sequences of H. pylori revealed the presence of only two Maf family homologues, HP0114 and HP0465 (Alm et al., 1999; Tomb et al., 1997). Significantly, while insertion inactivation of only HP0114 resulted in loss of motility, a novel metabolomic analysis of an isogenic HP0114 mutant revealed no effect on the production of CMP-Pse in the cytosol of the cell (Schirm et al., 2003). This is the first proof that while the Maf family of proteins clearly play a role in flagellar assembly they are not involved in the biosynthetic pathway of Pse.

Wolinella succinogenes. This is a Gram-negative commensal bacterium isolated from the bovine rumen and is a close relative of Campylobacter and Helicobacter. The flagellar structure of this polar-flagellated organism has received considerable attention due to its distinctive flagellar motor (for a review see Schuster & Khan, 1994). While no structural studies have been completed to date on the flagellin protein, bioinformatic examination of the W. succinogenes genome indicates that, as in Helicobacter and Campylobacter spp., it is likely that the structural proteins will also be glycosylated. The precise structure of the glycan found on these flagellin proteins may provide insight into the unique rumen niche in which the organism is found.

Aeromonas spp. Aeromonads are ubiquitous aquatic bacteria which can cause disease in fish, amphibians and reptiles. In addition, the mesophilic aeromonad species are significant human pathogens causing, most commonly, gastrointestinal infections but have also been associated with wound disease and septicemia (Thorlsey et al., 1997). Aeromonads are very efficient colonizers of surfaces and have been long recognized as key members of bacterial biofilms in both water distribution systems and food-processing environments. As with V. parahaemolyticus, two types of flagella have been shown to be responsible for motility. A polar unsheathed flagellum is expressed in broth culture or liquid environments (Rabaan et al., 2001), whereas the production of lateral flagella (laf) can be induced upon contact with solid surfaces or in the laboratory when the bacteria are grown on solid media (Kirov et al., 2002). Characterization of flagellar glycosylation systems has focused on the mesophilic aeromonads Aeromonas hydrophila and Aeromonas caviae. Polar flagella of both these species are complex, being composed of two structural proteins, FlaA and FlaB, and were shown by Rabaan et al. (2001) to be glycosylated based on periodate oxidation and reaction with biotin hydrazide. ‘Top-down’ mass spectrometry on purified flagellin has recently identified that up to six sites on FlaA and seven sites on the FlaB monomer are glycosylated with a derivative of Pse in O-linkage of mass 373 Da (Schirm et al., 2005). At the genetic level, a flagellar glycosylation operon was identified in A. caviae through a transposon mutagenesis study in which bacterial adherence was decreased. Insertional inactivation of three of the five genes in this operon resulted in loss of motility, and polar flagellin was no longer detected by immunoblotting in cell lysates, providing clear evidence for an integral role of glycosylation in filament assembly (Gryllos et al., 2001). As the structural analysis revealed that the protein was glycosylated with a derivative of Pse, it is not surprising that the genes in this locus show significant homology to the Pse biosynthetic genes of C. jejuni and H. pylori, namely pseB, pseC, neuA and neuB, as well as the flagellar glycosylation gene flmD from C. jejuni, H. pylori and Caulobacter crescentus, for which no precise function has been described. Laf of Aeromonas appear also to be complex in composition and again preliminary evidence has been presented indicating that the structural proteins may be glycosylated (Gavin et al., 2002). It remains to be established if the glycan(s) decorating the lateral flagellins are identical to that found on polar flagella.

Caulobacter crescentus. The unique developmental lifestyle of this aquatic bacterium, which includes the production of a unipolar, unsheathed, complex flagellar filament in only swarmer cell progeny, has resulted in a comprehensive analysis of the process of flagellum biogenesis in this organism (Gober & Marques, 1995). While the first description of a putative bacterial flagellar glycosylation locus can be attributed to C. crescentus and was presented by Leclerc et al. (1998) following earlier work in which the identification of a number of genes which affected flagellar assembly was made (Johnson et al., 1983), no definitive evidence for glycosylation of the flagellin proteins has yet to be presented. Orthologues of several of the genes identified in these studies which are present in a number of other bacterial species have since been shown to be involved in biosynthesis of flagellar glycans (FlmA, FlmB, FlmC, FlmD and FlmH). The polar filament of C. crescentus has been shown to be composed of three distinct structural proteins of molecular mass 29, 27 and 25 kDa (Driks et al., 1989); strains containing mutations in the putative glycosylation genes fail to assemble a flagellar filament and in some cases produce flagellins intracellularly

S. M. Logan
of reduced molecular mass. The three flm operons flmAB, flmEF and flmGH were shown to be regulated by CtrA, the transcriptional regulator which controls class II flagellar genes and as a consequence this novel group of genes was proposed to belong to a new class of flagellar genes in the _C. crescentus_ flagellar regulon. No structural characterization of the flagellin proteins from _C. crescentus_ has been completed to date, but the recent report of a role for flagella in initial attachment of these organisms to surfaces (Bodenmiller _et al._, 2004) raises the possibility that the glycan structure may indeed reveal important information on the mechanistic basis of this process.

**Pseudomonas** _spp._ In addition to being ubiquitous environmental organisms, a number of Pseudomonas species are opportunistic pathogens of both humans and plants, and motility appears to be critical to these processes. Motility is conferred on cells by either a single unsheathed polar flagellum or multitrichous polar flagella which are composed of a single flagellin structural protein, FliC. The flagellin proteins of the human pathogen _P. aeruginosa_ can be classified as either a-type or b-type based on their molecular mass and reactivity with polyonal antisera. Anomalous migration on SDS-PAGE was the first indication that the a-type flagellins were glycosylated (Totten & Lory, 1990) and subsequent studies have revealed the structural nature of the glycan found on these flagellin proteins and the type of glycosidic linkage (Schirm _et al._, 2004a). The structural characterization of PAK flagellin revealed a heterogeneous glycan comprising up to 11 monosaccharide units in O-glycosidic linkage which was attached through a rhamnose residue to the protein backbone at only two sites in the central, surface-exposed region of the protein monomer. In contrast to a second important cell-surface glycoprotein of _P. aeruginosa_, the pilin structural protein, which has been shown to be glycosylated with the O antigen repeat unit (Castric _et al._, 2001), the glycan decorating flagellin is unique in composition. This heterogeneous oligosaccharide was composed of pentose, hexose, hexuronic acid and deoxyhexose residues and was capped by a trisaccharide consisting of an aminodeoxyhexose, deoxyhexose and an unknown modification of molecular mass 174 Da. In a second a-type strain of _P. aeruginosa_, JJ692, the flagellin protein was glycosylated with a single rhamnose residue in O-linkage at two sites (Schirm _et al._, 2004a).

Mutagenesis studies of the PAK flagellar glycosylation island indicated that the addition of rhamnose to the flagellin protein appears to be a process independent of that for addition of the heterogeneous glycan. Glycosylation of _P. aeruginosa_ flagellin appears to have evolved into a two-stage process whereby initial glycosylation with a single rhamnose monosaccharide occurs and is likely common to all a-type strains. Additionally, the rhamnose moiety can be further modified through sequential extension, as was shown in the case of PAK, with a heterogeneous glycan capped with a conserved trisaccharide. In contrast to other species, where flagellar filament assembly is inhibited when the glycosylation process is interrupted, lack of glycosylation through mutation of the rhamnose-specific glycosyltransferase gene orfN from the flagellar glycosylation island had no effect on flagellar assembly or subsequent motility in _P. aeruginosa_.

Genetic studies have revealed considerable polymorphism in the glycosylation islands of a-type strains (Arora _et al._, 2004), indicative of considerable diversity in the composition of the respective flagellar glycans. The identification of a glycosylation island containing four genes, two of which display homology to genes within the PAK glycosylation island, from the genome of strain PAO, suggests that the flagellin from b-type strains may also be glycosylated.

In addition to the extensive structural characterization of flagellin it appears that glycosylation is important to virulence. In the burned mouse model of infection, genetically defined mutants which lacked flagellar glycosylation but still produced functional flagella were significantly attenuated in virulence (Arora _et al._, 2005).

The flagellins of the phytopathogenic bacteria _Pseudomonas syringae pv. glycinea_ and _pv. tomato_ have been shown to elicit hypersensitive cell death in non-host plants and recent work has clearly indicated that glycosylation of flagellin plays an integral role in this process and in host cell recognition. Genetic characterization of a putative glycosylation island of _P. syringae pv. glycinea_ revealed a key role for the process in virulence (Taguchi _et al._, 2003; Takeuchi _et al._, 2003). As with _P. aeruginosa_, glycosylation was not required for flagellar assembly. The structure of the glycan on respective strains remains to be elucidated but it is anticipated that it will be significant in understanding the specificity of pathovars for respective plant species.

**Azospirillum brasilense.** This organism is a nitrogen-fixing soil bacterium which colonizes plant roots and which like _Vibrio_ and _Aeromonas_ _spp._ is motile either by a single polar flagellum when grown in broth or, when grown on solid media, by laf. It has been shown that the polar flagellum is involved in adsorption of the organism to wheat roots (Croses _et al._, 2004). Preliminary evidence has also indicated that the structural protein is glycosylated through O-linkage, although the specific structure and degree of glycosylation on each monomer remains unknown (Moens _et al._, 1995).

**Agrobacterium tumefaciens.** Motility and chemotaxis have been long recognized as an important part of the ability of this well-studied plant pathogen to colonize the rhizosphere. Unlike enteric bacteria, but common to a number of rhizosphere-associated bacteria (e.g. _Sinorhizobium meliloti_ the flagellar structure and regulatory processes display a number of unique features (Krupski _et al._, 1985). The structure of the flagellar filament is complex and rotation of the polar flagella appears to be unidirectional.
Four flagellin structural proteins (FlaA, FlaB, FlaC and FlaD) have been identified within a flagellar locus and examination of the proteins by SDS-PAGE indicated an anomalous mass for the FlaA protein. Glycan staining of the gel revealed that this protein was glycosylated (Deakin et al., 1999). The structural basis of glycosylation and its biological role in colonization of the rhizosphere for both A. tumefaciens and related organisms remains to be established.

**Spirochaete periplasmic flagellins.** Preliminary evidence indicates that both FlaA (sheath protein) and FlaB (filament proteins) of the flagellins from a number of spirochaete species are glycosylated. Early work by Brahamsha & Greenberg (1988) utilizing lectin binding indicated that two of the three FlaB proteins of *Spirochaeta aurantia* were glycosylated based on reactivity with the lectin concanavalin A. Both FlaA and multiple FlaB flagellins of *Serpulina hyodysenteriae* (Li et al., 1993) were also shown to be glycosylated based on labelling studies and deglycosylation reactions. More recently, the structural FlaB flagellins of *Treponema pallidum* (Wyss, 1998) as well as the FlaA sheath protein of *Borrelia burgdorferi* (Ge et al., 1998) were shown to be glycosylated. While no detailed structural analysis of any spirochaete flagellin glycan has been completed, the reaction of *B. burgdorferi* FlaA protein with the lectins SNA (recognizes α(2-6) linked sialic acid residues) and GNA (recognizes terminal mannose) is indicative of a novel complex glycan structure. In addition, the sensitivity of this flagellar glycan to N-glycosidase F suggests that, as with the archaean flagellar glycan, the glycans of the FlaA protein may be present in N-glycosidic linkage (Ge et al., 1998). However, bioinformatic analysis of the six spirochaete genomes currently available at NCBI revealed no evidence of a conserved STT3 (pglB) oligosaccharide transferase gene in any of these genomes. This protein is required for transfer of N-linked glycans from the lipid carrier to asparagine of the protein (for a review see Szymanski & Wren, 2005). The precise chemical structure and type of glycosidic linkage found on both the FlaA sheath protein and individual FlaB filament proteins requires more extensive characterization as well as investigation into the role of this process in periplasmic flagellar assembly.

In summary, while there is currently no evidence for glycosylation of flagellins from the *Enterobacteriaceae*, polar flagella from a diverse range of other Gram-negative bacterial subdivisions appear to be glycosylated in O-linkage to serine/threonine residues. In bacteria which produce complex polar flagella (Campylobacter, Helicobacter, Aeromonas and Caulobacter), the process of glycosylation appears to be essential to the assembly process. In contrast, the glycosylation of the simple, polar flagella of *Pseudomonas* spp. is not essential to the assembly process. It remains to be established what type of glycosidic linkage is found on spirochaeta flagellins and if this process is an integral part of the periplasmic flagellar assembly process.

**Gram-positive bacteria**

In comparison to Gram-negative bacteria, only three Gram-positive bacterial genera have been shown to produce glycosylated flagellin. In contrast, the glycosylation of S-layer proteins has been extensively documented (Schaffer & Messner, 2004).

**Listeria monocytogenes.** This Gram-positive bacterium responsible for listeriosis can survive in numerous adverse environments including high salts, and pH and temperature extremes. The organism produces four to six simple peritrichous flagella when grown at <30 °C. Initial observations on SDS-PAGE of the flagellin protein indicated discrepancy in mass from that predicted (Dons et al., 1992; Peel et al., 1988) and prompted the structural characterization of purified flagellin protein (Schirm et al., 2004b). In distinct contrast to the previous examples, where either novel monosaccharides or complex glycans were shown to be attached to the flagellin protein, the flagellin of *L. monocytogenes* is glycosylated at up to six sites per monomer, which are localized to the central region of the protein, with β-1-O-linked GlcNAc. The addition of GlcNAc would not require a novel glycan biosynthetic pathway, as GlcNAc is a common biosynthetic precursor of many pathways, but the requirement for an O-GlcNAc transferase enzyme is of significance. No homologue of the well-characterized eukaryotic enzyme is present in the genome of *L. monocytogenes* strains although a candidate glycosyltransferase gene (Lmo0688) can be found close to the flagellin structural gene, fliC. It remains to be established if glycosylation is required for flagellar assembly in this organism. While motility is not considered of significance in human infection, the potential for a role of the glycosylation process in biofilm formation or colonization of surfaces at lower temperatures requires further investigation. In addition, binding via flagellar glycans to surface receptors of free-living protozoal hosts may be an important mechanism for entry and survival of a number of important bacterial pathogens such as *L. monocytogenes* (Inglis et al., 2003; Ly & Muller, 1990).

**Clostridium spp.** While little is known regarding the specifics of flagellar structures and organization amongst *Clostridium* spp., motility is a recognized feature of a number of members, including the important human pathogens *Clostridium botulinum* and *Clostridium difficile*, as well as the commercially relevant *Clostridium tyrobutyricum*, which is important in cheese spoilage, and *Clostridium acetobutylicum*, which is important for solvent production. Preliminary evidence for glycosylation of the flagellin protein from *C. tyrobutyricum* was presented by Bedouet et al. (1998) and Arnold et al. (1998). Non-reductive β-elimination of the flagellin protein revealed a mass shift and loss of binding of a monoclonal antibody, indicative of O-linked glycosylation which is part of the antigenic epitope recognized by the antibody. In addition, some alkali-resistant linked glycan was observed, suggestive...
of a second form of glycosylation. Analysis of *C. acetobutylicum* flagellin indicated that the protein is modified with an additional 12 kDa of modification which is sensitive to periodate oxidation. This glycan modification was insensitive to N-glycosidase F, endoglycosidase H and O-glycosidase yet was sensitive to neuraminidase treatment, indicating that a 'sialic acid like' sugar is a glycan component (Lyristis *et al.*, 2000). Bioinformatics analysis of the recently completed genomes of *C. botulinum* and *C. difficile* has identified a number of glycan biosynthetic genes within the flagellar biosynthetic loci, indicating that glycosylation may be an integral part of the respective motility systems found in these organisms (S. M. Logan, unpublished data).

*Butyrvibrio fibrisolvens.* The flagella of this Gram-positive rumen anaerobe have been described as subpolar and complex in nature, with two flagellin structural genes identified and sequenced. In addition, the flagellin proteins were shown to be glycosylated using a DIG glycan detection kit (Kalmokoff *et al.*, 2000). The structural basis of this glycosylation is currently unknown.

The genetic and structural characterization of flagellar glycosylation systems of Gram-positive bacteria is clearly still in its infancy although the examples described here indicate that, as with Gram-negative bacteria, the glycans are attached via O-linkage. The role of this process in flagellar assembly and its contribution to biological interactions for respective organisms remain to be determined.

**O-Glycosidic vs N-glycosidic linkage of flagellar proteins**

It is clear from the body of work presented in this review that the glycosylation of bacterial and archaeal flagellins appears to occur via two unique processes which are the consequence of the distinct mechanisms of assembly for the respective flagellar structures. The incorporation of archaeal flagellins into the growing filament occurs following cleavage of the preflagellin signal sequence in a similar fashion to that described for type IV pili (for a review see Craig *et al.*, 2004). Glycosylation of the mature flagellin protein likely occurs in typical N-linked fashion at the periplasmic face of the inner membrane, where the oligosaccharyltransferase (PglB) transfers the assembled glycan from a lipid-linked carrier to the protein backbone (for a review see Szymanski & Wren, 2005). However, the mechanistic basis for specific targeting of a limited number of proteins to the glycosylation machinery remains to be determined; many proteins are secreted from the cell and would be associated with the periplasmic face of the cell membrane during this process.

In contrast, the O-glycosylation of bacterial flagellin appears to be a far more compartmentalized/sequestered event. To date, no reports of other cellular bacterial proteins carrying the same O-glycan have been reported in any of the aforementioned bacterial species (with the exception of the flagellar hook protein of *H. pylori*; personal observation).

The detailed mechanistic studies of flagellar assembly have revealed that newly synthesized flagellin protein is prevented from premature monomer interaction in the cytoplasm as a consequence of interaction with FliS, the cytosolic chaperone protein which binds to a C-terminal 40 amino acid region (Evdokimov *et al.*, 2003; Ozin *et al.*, 2003). Targeting of the flagellin monomers to the export apparatus is mediated by specific N-terminus sequence recognition and the protein is secreted through the type III secretion system pore/basal body structure along the hollow core of the growing filament to the tip, where it is then incorporated (Macnab, 2003). It is difficult to conceive that glycosylation of the protein would take place at the tip of the filament and at no time are these flagellins exposed to the periplasmic face of the inner membrane, so our current working hypothesis is that O-glycosylation takes place either in the sequestered basal body environment (either external to the cell membrane or as the protein monomer passes through), or at the cytoplasmic face of the inner membrane in the close vicinity of the basal body. This would permit the assembly of complexes required for the process of glycosylation, in particular for the type of complex glycans composed of multiple monosaccharides as exemplified by *P. aeruginosa* PAK flagellin. A hypothetical and somewhat speculative model comparing the archaecal and bacterial processes is presented in Fig. 1. For the bacterial flagellin glycoproteins characterized to date it is apparent that the sites of O-glycosylation are likely localized to surface-exposed domains of the flagellin protein assembled in the flagellar filament (Samatey *et al.*, 2000). Whether this is a consequence of the conserved functional requirements of specific sequences at N- and C-termini, which are essential for critical monomer–monomer interactions within the filament, or the state of the protein (either unfolded or partially folded) when it comes into contact with the specific glycosyltransferases remains to be established, although a recent study on pilin glycosylation in *Pseudomonas* indicated that the pilin is folded prior to glycosylation (Horzempa *et al.*, 2005). It should be emphasized that in the current model presented in Fig. 1, while we suggest that the chaperone–flagellin interaction may prevent glycosylation of C-terminal regions, it is currently unclear what state the flagellin protein is in during transit through the central channel. Additionally, our current knowledge of O-glycosylation has failed to identify any consensus sequence. It remains to be established what contribution the specific folded state of the protein and local environment of serine/threonine residues makes, in addition to distinct substrate specificities of each respective glycosyltransferase enzyme, to the glycosylation process.

**Glycoengineering**

Along with the recent exploitation of the novel bacterial N-linked general protein glycosylation system of Campylobacter for the production of glycoproteins of relevance in antimicrobial therapy (Feldman *et al.*, 2005), the flagellar N-linked systems of Archaea and the bacterial flagellar O-linked process described here also have considerable
potential. Both novel structures and novel biosynthetic enzymes which may have application in glycoengineering have already been revealed. In the study of M. voltae flagellar glycosylation, it was demonstrated that β-GlcNAc was the linkage sugar to Asn for each N-linked sequon. This linkage is commonly found in many eukaryotic systems for the attachment of the complex polymannose oligosaccharides which have considerable biological significance and so points to the potential of utilizing recombinant enzymes from these organisms for glycoengineering purposes. It is

---

**Fig. 1.** Schematic representation of a speculative model for O- and N-linked flagellar glycosylation. (A) In Bacteria, O-linked flagellin glycosylation is proposed to occur at the cytoplasmic face of the inner membrane in the vicinity of the basal body/type III secretion complex. Nucleotide-activated sugars are added to serine and threonine residues which are surface exposed in the flagellin protein–chaperone complex by specific glycosyltransferases of the glycosylation machinery. These glycosylated flagellin monomers are then secreted through the basal body and hook regions to the filament tip, where they are incorporated into the growing filament. Flagellin monomers in the cytosol interact with a flagellin-specific chaperone protein (orange) to prevent premature polymerization (adapted from MacNab, 2003). Grey and black subunits represent different flagellin structural proteins of complex flagellar structures. In the assembled filament, the N- and C-terminal regions which constitute the D0 and D1 domains are internal and not exposed at the surface. OM, outer membrane; PG, peptidoglycan layer; CM, cytoplasmic membrane. (B) In Archaea, N-linked glycosylation is proposed to occur at the outer face of the cell membrane. The assembly of the glycan occurs on a lipid-linked carrier in the cytoplasm and is then ‘flipped’ across the inner membrane by an ABC transporter in a similar fashion to N-linked glycosylation of Campylobacter. The flagellin monomer, which is synthesized as a preflagellin with a short positively charged leader peptide, is glycosylated by an oligosaccharyltransferase enzyme (OTase, an orthologue of PglB from C. jejuni) at the outer face of the cell membrane prior to incorporation into the flagellar filament. In contrast to the bacterial filament, the archaeal filament lacks a central channel and it is believed that newly synthesized monomers are incorporated at the base at the outer face of the membrane. PG, peptidoglycan layer; SL, S-layer. (Adapted from Thomas et al., 2001; reprinted with permission from the Annual Review of Microbiology, volume 57 © 2003 by Annual Reviews www.annualreviews.org/).
noteworthy that BLAST analysis of current bacterial genome databases reveals a large number of environmental isolates which contain homologues of a number of flagellar glycosylation genes or genes with homology to glycan biosynthetic genes. These organisms may provide a diverse source of novel structures and enzymes with unique properties for glycoengineering purposes. The identification of β-O-linked GlcNAc on *L. monocytogenes* flagellin points to the potential of this system for exploitation in recombinant biosynthesis of relevant eukaryotic nuclear and cytosolic O-linked glycopeptides carrying this important modification.

The identification of the ald-2-ulosonic acid, Pse and related derivatives on the flagellin of a number of organisms is also of relevance for glycoengineering applications. Deoxysugars, which are formed from common monosaccharides in plants, fungi and bacteria, are now recognized as an important unique class of bioactive molecules with great potential, most notably in the glycosylation of antibiotics and in the development of novel anticancer drugs (Salas et al., 2005; Trefzer et al., 1999). The recent demonstration of the exquisite specificity of dehydratase/aminotransferase enzyme pairs from the Pse and related bacillosamine pathways (Schoenhofen et al., 2006) adds to the biosynthetic toolbox for the synthesis of these unique bioactive molecules.

These flagellar systems also offer the potential to express in high quantities a recombinant glycopeptide within an immunodominant bacterial protein for presentation to the immune system. It has been shown that the central region of the flagellin monomer can be utilized for recombinant expression of novel peptide antigens (Cattozzo et al., 1997; Newton et al., 1995). With the identification and characterization of flagellar-specific O-linked glycosylation systems, the potential now exists to expand such a process to a glycopeptide expression system.

**Novel bacterial therapeutic targets**

A number of the organisms described in this review which produce glycosylated flagellins are significant human pathogens. There is clear evidence that the glycosylation process is either essential for flagellar assembly and subsequent colonization (Schirm et al., 2003; Thibault et al., 2001) or plays a role in virulence of these pathogens (Arora et al., 2005; Rabaan et al., 2001). As a consequence, small-molecule inhibitors of the respective biosynthetic pathway enzymes or the glycosyltransferases responsible for the addition of glycan to the protein offer potential as novel therapeutic agents in much the same way as has recently been suggested for type III secretion systems (Kauppi et al., 2003; Nordfelth et al., 2005). The detailed functional characterization for the enzymes responsible for the initial steps in the Pse biosynthetic pathway may provide such targets for the design of small-molecule inhibitors which will prevent flagellar assembly and consequently prevent the colonization of the gastrointestinal tract by *C. jejuni* and *H. pylori* (Chou et al., 2005; Schoenhofen et al., 2006).

**Closing remarks**

Flagellar glycosylation can no longer be considered a rare anomaly found in only a few bacterial species with little biological relevance. Not only has the process been shown to be integral to the assembly of complex, polar flagella; the diversity of glycan structures found on organisms from unique environments points to novel biological roles which have yet to be revealed. It has been clearly demonstrated that the flagellin secreted by the flagellin-specific type III pathway can be glycosylated, and so it is tempting to speculate that glycosylation of other proteins secreted either by this pathway or other type III secretion systems may also occur. As yet no evidence for this has been presented although the biological advantages of glycosylation for secreted proteins may be substantial: for example targeting to receptors, increased stability, resistance to proteolysis, immune regulation. If indeed nature has not taken advantage of this process, the potential of such a system from a glycoengineering perspective remains to be realized.

**Acknowledgements**

I would like to thank my colleagues John Kelly and Pierre Thibault for their valuable contributions in mass spectroscopy analysis. In addition, I thank Ian C. Schoenhofen for his critical reading of this review. I am grateful to T. Devesceri for his help with figure preparation.
