Observations on the Effects of a Chromosome Duplication in *Aspergillus nidulans*

BY B. W. BAINBRIDGE* AND J. A. ROPER

Department of Genetics, University of Sheffield

*(Received 4 October 1965)*

**SUMMARY**

During a study of genetic factors affecting the morphology of *Aspergillus nidulans* a novel and characteristic variant was observed among the progeny of crosses involving certain morphologically normal parents. This type, which had a diminished linear growth rate, segregated in constant proportion; it was designated 'crinkled'. It carried a duplication for a chromosome segment as a result of an unequal translocation in one parent. Crinkled colonies showed vegetative instability and sectored types which, in varying degree, approached normal morphology and growth rate. These revertants probably arose by loss of a variable part of the chromosome segment carried in duplicate. The loss occurred from either the translocated or untranslocated segment.

**INTRODUCTION**

During a study of genetic factors affecting morphology in *Aspergillus nidulans* a novel and characteristic variant, designated 'crinkled' (*cr*); was observed; *cr* types posed two main problems. They arose regularly and in constant proportion from crosses of particular parents which had normal morphology. Furthermore, *cr* colonies showed vegetative instability in giving sectors which, in varying degree, approached normal morphology and growth rate. The present paper describes an investigation into the genetic determination of *cr* and the nature of its instability.

**METHODS**

The general techniques used in this work were those of Pontecorvo *et al.* (1958). Incubation was at 37°.

**Media.** Minimal medium (MM), Czapek-Dox with 1% glucose. Complete medium (CM), a complex medium containing yeast extract, hydrolysed casein, hydrolysed nucleic acid, vitamins, etc. Solid media contained 2% agar.

**Organisms.** *Aspergillus nidulans* strains were maintained on CM. Details of mutant alleles, and their locations, are given by Pontecorvo *et al.* (1958), Roper & Käfer (1957), Käfer (1958) and Warr & Roper (1965). Käfer (1961, 1962a, b, 1965) described the chromosome translocations in many of the currently used strains.

The mutants of main importance in this work were: *y*, yellow conidia; *cha*, chartreuse conidia; *w2* and *w3*, white conidia; *ad3* and *ad20*, *arg1*, *bi1*, *cys2*, *lys5*.

* Present address: Department of Microbiology, Queen Elizabeth College, Campden Hill Road, London, W. 8.
nic2 and nic8, paba6, phen2, pro1, pyro4 and pyro12, ribo1 and ribo2, s1, s3 and s12, growth requirement, respectively, for adenine, arginine, biotin, cystine, lysine, nicotinic acid, p-aminobenzoic acid, phenylalanine, proline, pyridoxin, riboflavine and sulphite; su1-ad20, suppressor of ad20; Acr1, resistance to acriflavine. Translocations are designated by the symbol (T) after the genotype.

Genetic analysis. The general techniques of analysis used were those of Pontecorvo et al. (1953) with modified techniques for ascus dissection (Bainbridge, 1964) and for certain crosses (Bainbridge, 1965).

RESULTS

The segregation of crinkled

Table 1 shows the segregations from a number of crosses between particular parents with normal morphology. The cr segregants had a characteristic phenotype (Pl.1, fig. 1) and a diminished linear growth rate; cr segregants from the five crosses were phenotypically indistinguishable, suggesting a common mode of origin. However, in case they differed in origin, cr segregants were numbered consecutively at isolation.

* χ² test for fit to 2:1 ratio of normal:crinkled. Results from the last two crosses were kindly supplied by Dr J. R. Warr.

The segregation data were statistically inconsistent with 1:1 or 3:1 ratios but showed good agreement with a ratio of 2 normal:1 cr. This suggested the possibility of two freely-recombining interacting genes in which one recombinant class was nonviable and the other cr. Ascus analysis was undertaken on only a small scale. However, the results indicated inviability of a type which could not be ascribed readily either to technique or to chance inviability of a proportion of ascospores. From the cross, b11 × y; ad3; s1 cys2, four classes of ascus were found in the 10 asci analysed. Five ascus were of type I with 4 spore pairs giving morphologically normal colonies; 1 type II ascus with 2 cr, 2 nonviable spore pairs; 2 type III ascus with 2 normal, 1 cr, 1 nonviable spore pairs and 2 type IV ascus with 4 nonviable spore pairs. These segregation patterns corresponded to ascus showing the following spore sizes: I, 8 normal; II, 4 normal, 4 small; III, 6 normal, 2 small, and IV, 8 small. Overall ascospore viability, both from ascus analysis and random spore platings, was about 60%.

Two freely-recombining genes with the interactions outlined above would yield ascus of types, I, II and III but type IV would not be expected and it was necessary
A chromosome duplication in aspergillus

to seek an explanation of cr in other terms. The data of Käfer showed that in all the
crosses of Table 1 one or other parent carried a chromosome translocation involving
linkage groups III and VIII and it seemed reasonable to explore the possible
association of this translocation and cr. Pritchard (1960; and personal communica-
tion) had already reported a strain of Aspergillus nidulans carrying a chromosome
duplication and with a morphology somewhat similar to cr. Furthermore, from a
cross in Neurospora crassa involving an unequal translocation in one parent,
McClintock (1945) reported ascus analysis data similar in patterns of defective
spores to those given above.

Many crosses were examined for the segregation of cr but consideration will be
given here only to those crosses involving parents of known status in respect of the
III–VIII translocation. There were 28 crosses involving 27 different, morpho-
logically normal parent strains. Those crosses in which both parents or neither parent
carried the translocation did not yield cr segregants; all crosses in which only one
parent carried the translocation did yield cr among the progeny.

The segregation data could be accommodated if the translocation were unequal.
A cross heterozygous for this translocation would yield 25% of the progeny with a
deficiency and 25% with a duplication. The former would certainly be nonviable and
the latter, presumably, cr. It remained to test this idea and to determine the
direction of the III–VIII translocation. Mitotic haploidization is used to detect
heterozygous translocations (Käfer, 1962 b). During haploidization of diploid nuclei of
Aspergillus nidulans there is no crossing-over and markers on the two linkage
groups involved in a translocation show complete linkage, in contrast to the free recombi-
nation expected in translocation-free diploids. However, this first analysis did not
reveal either the direction or extent of the translocation.

(T) indicates a strain carrying the III–VIII translocation.
* χ² test for agreement with 1:1 ratio.

As a first step towards testing the idea of an association of cr and a chromosome
duplication, cr segregants from various crosses were backcrossed to strains of
normal morphology with or without the III–VIII translocation. In both types of
cross the only chromosomal difference between the parental strains of each cross
was the suspected presence of a duplicated chromosome segment. A 1:1 ratio of cr
type to normal was therefore expected in the progeny. Table 2 shows a selection
of the results obtained and these are all consistent with the expected ratio. Certain
anomalous backcross results, obtained in other crosses, are discussed later.
Anomalous segregations of nutritional markers among cr progeny

Normal and cr progeny from various crosses of normal parents were classified for the segregation of a number of nutritional markers. Allele ratios for both morphological classes were 1:1 except in the case of cys2 which is located on the right arm of linkage group III. From a cross of an untranslocated strain to a strain carrying cys2 and the III-VIII translocation, normal and cr segregants were tested for cystine requirement. This marker gave a 1:1 segregation among morphologically normal progeny but of 70 cr segregants only 6 required cystine. This suggested that

![Diagram]

Fig. 1. Aspergillus nidulans. A diagrammatic representation of the origin of cr and revertants of cr. Broken and unbroken lines represent chromosomes III and VIII respectively.

the second parent in the above cross had a translocation to chromosome VIII of the segment of chromosome III which carries cys2. The cr segregants would then carry this segment of chromosome III in duplicate (Fig. 1). Most cr segregants would be cys2/cys2+ and only those which resulted from crossing-over between cys2 and the point of translocation, followed by appropriate segregation, would be cys2/cys2. The alternative, a translocation from chromosome VIII to chromosome III, would have given cr types with duplication of a segment of chromosome VIII. In this case at least 50% of cr segregants would have required cystine. The frequency of cr, cystine-requiring segregants gave a measure of the extent of the translocation and indicated that cys2 shows about 17% recombination with the point of break.

A number of cystine-independent cr segregants were selected from crosses involving the marker cys2. Each was crossed to a morphologically normal, cystine-independent strain with the III–VIII translocation. Several crosses gave no segregants requiring cystine and the cr parents in these were presumably cys2+/cys2+. Two crosses yielded cystine requirers. Of 25 normal segregants from the cross, cr15 pro1 y x b11; w6; pyro12, 12 required and 18 were independent of cystine. From the cross, cr29 b11; w2; arg1 x ad8, both crinkled and normal segregants were
A chromosome duplication in Aspergillus 421

classified. The normal segregants were 23 independent and 14 requirers while of 29 crinkled segregants tested only 1 required cystine. These crosses showed unequivocally that certain cr strains were heterozygous cys2/cys2+ and carried, therefore, a duplication for a segment of chromosome III.

Instability of cr strains

Table 3 lists further segregations from backcrosses of cr strains and the results are in sharp contrast to those of Table 2. These results indicated possible instability of cr strains; they were later explained in terms of vegetative instability.

† Results from different individual perithecia.

Three cr strains were selected from the cross bi1; w3; cys2 (T) x y, ad3; s1. Each was inoculated at a single point in the centre of several plates of CM. After 10-days incubation more than half of the colonies showed 'revertant' sectors (Pl. 1, fig. 2). The cr parents had a linear growth rate about 53% that of wild type and the revertant sectors ranged between 58 and 97% of wild type. All the revertant sectors could still be distinguished from the morphologically normal parents in showing some degree of the general phenotypic features of cr. It seemed likely that reversion could be explained in one of two ways. Revertants might arise from mutations which suppressed, in varying degree, the morphological effects of the duplication. Alternatively, there might have been loss at mitosis of a part, presumably a variable part, of one of the chromosome segments carried in duplicate.

A number of cr segregants were selected from the cross bi1; w3; cys2 (T) x y; w2; arg1. These segregants, and revertants derived from them, were classified for cystine requirement with the results shown in Table 4. cr strains 34, 35 and 36 are presumably cys2/cys2 in genotype; the genotypes of strains 25, 26, 28, 30 and 33 cannot be determined from the data available; 23, 29 and 31 showed vegetative segregation indicating a genotype cys2/cys2+. These results confirmed the duplication, in cr strains, of a segment of chromosome III and they also strongly indicated the process of reversion. It seemed highly probable that the revertants arose by loss, at mitosis, of part or all of the duplicated chromosome segment. Furthermore, cr31 and cr29 segregated both cystine-requiring and cystine-independent revertants indicating that the proposed chromosome loss could take place from either the translocated or untranslocated segment.

In an attempt to confirm this last point, three of the revertants from cr29 were
crossed to morphologically normal strains with or without the III–VIII translocation. The results are shown in Table 5; no distinction was made in classification between segregants with revertant and those with wild type morphology. Revertants 2 and 14 gave segregations consistent with a 2:1 ratio when crossed with an untranslocated strain but not when crossed with a strain carrying the translocation. The reverse situation obtained for revertant 12. These results could be explained in the terms shown diagrammatically in Fig. 1. cr29 is shown with a duplication of a segment of chromosome III. It was certainly heterozygous cys2/cys2+ and it was highly likely, from consideration of its pedigree, that cys+ was carried on the untranslocated segment. In crosses with translocation-free strains, R2 and R14 behaved like morphologically normal strains carrying the III–VIII translocation; they yielded a 2:1 ratio of normal:cr. They had presumably lost, from the previously intact chromosome III, most of that segment of III which was also represented in the translocation to VIII. However, they could not have lost the whole of the segment. From crosses with normal strains carrying the translocation they yielded a low frequency of cr segregants and this would not have been the case for two morphologically normal translocated parents. The low proportion of cr could

A chromosome duplication in aspergillus

A chromosome duplication in aspergillus arise by crossing-over in, and appropriate segregation from, the quadrivalent formed at meiosis. A similar argument could be applied to $R12$ except that in this case the behaviour of the revertant approached that of an untranslocated normal strain; it yielded very low frequencies of $cr$ segregants in a cross with a translocation-free strain and gave a 2:1 ratio normal:$cr$ in a cross with a normal strain carrying the translocation.

It was suggested earlier that mutations at suppressor loci might be invoked to explain reversion. It could be supposed that such mutations would completely or partially suppress the phenotypic effects of the duplications. The results of Tables 4 and 5 excluded the possibility of suppressors which recombined freely with the point of translocation. To maintain this possibility, in view of the vegetative segregation shown in Table 4, it would have been necessary to suggest that each suppressor was specific for one or other of the duplicated segments; this seemed very unlikely. Moreover, certain crosses of revertants (Table 5) yielded only a low frequency of $cr$ segregants; a freely-recombining suppressor would have yielded a far higher frequency. However, there remained the possibility, admittedly remote, that reversion might be explained not by chromosome loss but by mutations at suppressor loci linked to one or other duplicated chromosome III segment. Such mutations would have to suppress both the linked $cys$ allele and the phenotypic effects of the segment of chromosome distal to the point of mutation. $R14$ required cystine; on the basis of this argument it would have carried a suppressed $cys^{2+}$ allele which it should have been possible to reveal in appropriate crosses. $R14$ was crossed with $bil; cys^{2}; lys^{5}; cha$ and a total of 20,000 ascospores, of hybrid origin, plated on MM supplemented with all requirements except cystine. From platings at various concentrations no cystine-independent segregants were recovered.

DISCUSSION

The observed morphological effects of a chromosome duplication were not surprising since such effects are well known in a wide variety of organisms. However, the vegetative instability was unexpected. So far we have observed this instability through the sectors formed from $cr$ colonies. Our data do not permit a calculation of the reversion rate. Such a calculation could be based on the frequency of revertants obtained by plating conidia from $cr$ strains. Both from such platings, and from the frequency of sectors yielded by $cr$ colonies, it may also be possible to investigate genetic and environmental factors which influence the reversion rate. For the present we can only say that the frequency of spontaneous reversion of $cr$ was far greater than that of gene-determined slow-growing variants.

Reversion could best be explained by spontaneous chromosome or chromatid breakage, followed by loss of the fragment at mitosis. It could also be explained by an error in replication which resulted in a break in the continuity of the chromosomal material. We were fortunate in having a system which selects for revertant events but our results do not yet permit distinction between these two possible modes of origin.

When this work was done there were few known markers on the relevant segment of chromosome III. A search is now being made for further markers in this segment and for a similar situation involving other well-marked chromosome segments. It
should then be possible to define the positions of chromosome loss more precisely. Such a system might lend itself to a study of chromosome structure, especially if it were possible to find agents or conditions which selectively produced losses in particular regions of the duplicated segment. The positions of loss would correspond to points sensitive either to breakage or to the interruption of replication.

The authors are grateful to Dr A. J. Clutterbuck and Dr J. R. Warr for valuable discussions. They are particularly indebted to Dr E. Käfer-Boothroyd who made strains and unpublished data freely available; without this help the work could not have been completed. An A.R.C. Postgraduate Studentship to one of us (B. W. B) is gratefully acknowledged.
